6. One reason Viagra was no more effective than a placebo in improving female sexual functioning is that Viagra essentially deals with the flow of blood into and out of sexual organs and doesn't seem to improve sexual desire. Thus, women's low sexual desire or motivation, which may be a psychological problem, is a difficulty that Viagra doesn't seem to help.

Emotional Experience

What did Bethany feel during a shark attack?

What happened to Bethany Hamilton at 7:30 on a Friday morning was something she would never forget. Bethany paddled her surfboard about a quarter-mile off the north shore of Kauai, Hawaii, and as she waited to catch the best waves, she noticed the water was clear and calm, like a swimming pool. The waves turned out to be too small to ride so she relaxed by holding the surfboard with her right arm and letting her left arm dangle in the warm water. Suddenly she saw a glimmer of gray in the clear blue water. Almost instantly, Bethany felt tremendous pressure and fierce yanking on her left arm. It was then she realized that the razor-sharp teeth of a 15-foot tiger shark were wrapped tightly around her left arm. When she saw the water around her turn bright red with streaks of her blood, her heart pounded like a hammer and her adrenaline flowed like water from a fire hose. The shark eventually let go of her arm and swam away. With great courage and perseverance, Bethany paddled to the beach as quickly as she could with only her right arm. Her left arm had been violently ripped off almost to the armpit, and the shark even took a big chunk out of her surfboard!

As Bethany approached the beach, people helped her off the surfboard and called for help. She was rushed to the hospital for surgery, and about a week after her stitches were removed, Bethany began surfing again. It was difficult learning to surf with only her right arm, but her extraordinary drive helped her win several surfing competitions after the attack. Although Bethany at times experiences dread and fright that something bad is going to happen again, for the most part, she is as comfortable as other surfers are while in the water (adapted from B. Hamilton, 2004).

Bethany was attacked by a shark, which bit off her entire left arm!

Bethany experienced a variety of emotions during and after her shark attack. During the attack, she felt intense anxiety and fear for her life. When she reached the shore, she felt relieved to be alive but worried about her missing arm. Sometime later, she felt fright about surfing again, but she also felt pride and joy after catching her first big wave after the attack. Although Bethany experienced over a half-dozen emotions, they all shared the same four components (Frijda, 2008).

An ***emotion*** is defined in terms of four components. First, you interpret or appraise some stimulus (event, object, or thought) in terms of your well-being. Second, you experience a subjective feeling, such as fear or happiness. Third, you have physiological responses, such as changes in heart rate or breathing. Fourth, you may show observable behaviors, such as smiling or crying.

Bethany's experience with the shark illustrates the four components of an emotion:

First, she ***interpreted*** or ***appraised*** the stimulus, a shark attack, as a very serious threat to her well-being and survival.

Second, she had the ***subjective experience*** or ***feeling*** of fear and terror.

Third, she had a variety of ***physiological responses,*** such as heart pounding and adrenaline pumping, which cause arousal and prepare the body for action, such as swimming away fast.

Fourth, she showed ***overt*** or ***observable behaviors,*** such as fearful facial expressions and rapid paddling to the beach. In some cases, such as playing poker, a person may experience a wide range of emotions but try to hide his or her overt behaviors by showing no facial expression, commonly known as a "poker face." In other cases, cultural factors influence overt behaviors, such as allowing American women but not usually American men to cry in public.

Although there is general agreement that emotions have four components, there is much discussion of the order in which these four components occur (Frijda, 2008). For instance, did Bethany have to think about the shark before she felt fear, or did she feel fear immediately and then think about how terrified she was? We'll discuss this as well as many other questions about emotions, such as why people can identify a fearful face quicker than a happy one.

Staying Happy

How long do emotions last?

Being attacked by a shark results in a very different emotional experience than winning big bucks in a lottery. Since lotteries began in the late 1970s, over 4,000 people have become instant millionaires. Immediately after winning, the new millionaires reported feeling intense pleasure, being ecstatic, and living in a dream world (Angelo, 1991). But what happens when a winner finally realizes that for the next 20 years he or she will receive a large monthly check? Will the emotional high continue, or will being a millionaire become a taken-for-granted experience?

Ten years after winning a $20-million lottery, would you still be very happy?

Researchers have studied lottery winners to find out what effect such an enormous windfall has had on their lives (CPO, 2006). Later in this module, we'll tell you what the researchers discovered about happiness and how it applies to lottery winners and you.

What's Coming

We'll discuss how emotions occur; how much our physiological responses, facial expressions, and interpretations contribute to emotions; whether feeling or thinking comes first in experiencing an emotion; whether there is a set of basic or universal facial expressions that occur across all cultures; what the functions of emotions are; how specific emotions work; and how emotions are used in lie detection.

We'll begin our discussion of emotions with how a swimmer's sight of a shark causes him or her to feel fear.

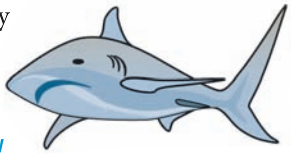
A. Peripheral Theories

Studying Emotions

Why do you feel fear?

Seeing a shark swimming nearby causes instant fear. Explaining how this fear arises has taken three different approaches.



The ***peripheral theories of emotions*** emphasize how physiological changes in the body give rise to emotional feelings.

The ***cognitive appraisal theory of emotions*** emphasizes how interpretations or appraisals of situations result in emotional feelings.

The ***affective neuroscience approach*** studies the underlying neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to experiencing and expressing different emotional states.

We'll begin with one of the peripheral approaches to understanding emotions, the historic James-Lange theory, which says that if you see a bear, you are frightened because you run. Is it true?

James-Lange Theory

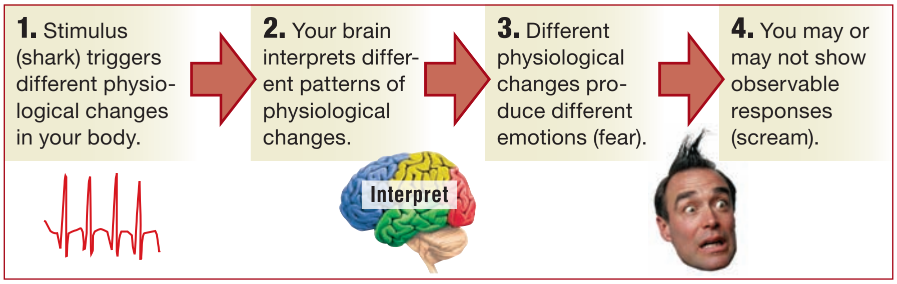
This theory, proposed independently in the late 1800s by two psychologists, William James and Carl Lange, emphasizes specific physiological patterns as causing emotional feelings.

The ***James-Lange theory*** says that our brains interpret specific physiological changes as feelings or emotions and that there is a different physiological pattern underlying each emotion.

James (1884/1969) illustrated his theory with the example of seeing a bear: If you see a bear, "you are frightened because you run" rather than run because you are frightened. According to the James-Lange theory, the order for the occurrence of the four components of an emotion is shown in the right figure.

Criticisms. There are three major criticisms of the James-Lange theory. First, different emotions are not necessarily associated with different patterns of physiological responses. For instance, anger, fear, and sadness share similar physiological patterns of arousal (Cacioppo et al., 2000). Thus, James's bear example was backward: Instead of the act of running making you feel fear, you feel fear and then run.

Second, people whose spinal cords have been severed at the neck are deprived of most of the feedback from their physiological responses (autonomic nervous system), yet they experience emotions with little or no change in intensity. These data are the opposite of what the James-Lange theory would predict, which is that these people should experience little or no emotion (Chwalisz et al., 1988).



1. Stimulus (shark) triggers different physiological changes in your body.

2. Your brain interprets different patterns of physiological changes.

3. Different physiological changes produce different emotions (fear).

4. You may or may not show observable responses (scream).

Third, some emotions, such as feeling guilty or jealous, may require a considerable amount of interpretation or appraisal of the situation. The sequence involved in feeling a complex emotion like guilt or jealousy points to the influence of cognitive factors on emotional feelings (Clore & Ortony, 2008).

Intensity. Although researchers showed that physiological changes are not the primary cause of emotions, physiological changes (heart pounding, sweaty palms) may increase the intensity of emotional experiences (Larsen et al., 2008).

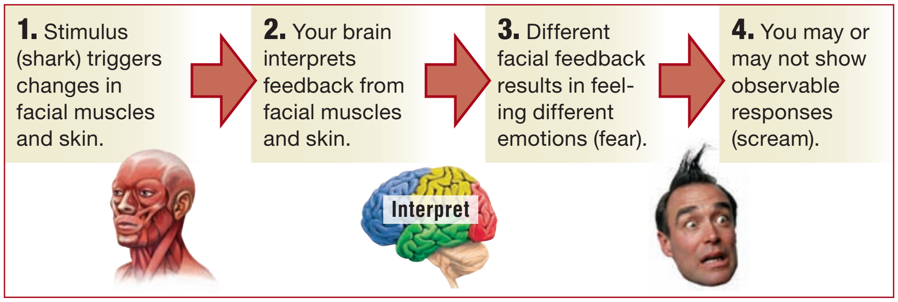
Next, we turn to the second peripheral theory, the facial feedback theory, which offers a different explanation of how emotions occur.

Facial Feedback Theory

The idea that feedback from facial muscles causes emotional feelings originated with Charles Darwin (1872/1965) and evolved into facial feedback theory (Keltner & Ekman, 2000; Matsumoto et al., 2008).

The ***facial feedback theory*** says that the sensations or feedback from the movement of your facial muscles and skin are interpreted by your brain as different emotions.

According to facial feedback theory, the four components of emotions occur in the order shown in the figure below.



1. Stimulus (shark) triggers changes in facial muscles and skin.

2. Your brain interprets feedback from facial muscles and skin.

3. Different facial feedback results in feeling different emotions (fear).

4. You may or may not show observable responses (scream).

Criticisms. While it is true that facial expressions of fear, happiness, sadness, and disgust involve different muscle-skin patterns, there is little evidence that it's the feedback from these different muscle groups that actually causes the emotion. For example, if feedback from facial muscles caused emotions, then individuals whose facial muscles are completely paralyzed should not be able to experience emotions, yet they do report feeling emotions (K. M. Heilman, 2000).

Although researchers have not confirmed Darwin's original theory that feedback from facial muscles ***alone*** is sufficient to produce emotions, they have found that feedback from facial muscles, such as those involved in smiling or crying, may influence your mood and overall emotional feeling and increase the intensity of your subjective emotional experience (Kolb & Taylor, 2000).

The peripheral theories of emotions show that physiological changes in the body and feedback from facial muscles contribute to but do not themselves cause different emotions. What can cause an emotion are the thoughts that go on inside your brain (mind).

B. Cognitive Appraisal Theory

Thoughts and Emotions

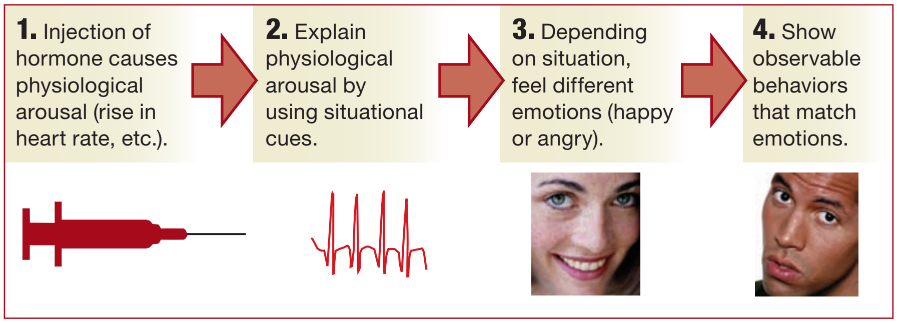
Can thoughts cause emotions?

Suppose you won a lottery and felt very happy. Weeks later, the thought of winning still makes you feel very happy. The fact that your thoughts alone can give rise to emotions illustrates the importance of cognitive factors.

Current cognitive theories of emotions can be traced back to the original research of Stanley Schachter and Jerome Singer (1962), whose classic experiment was the first to show the importance of cognitive interpretation, or appraisal, in contributing to emotional states.

Schachter-Singer Experiment

As shown in the figure below, Schachter and Singer first injected their subjects with a hormone, epinephrine (adrenaline), that caused physiological arousal, such as increased heart rate and blood pressure. However, subjects were told that the injections were vitamins and were not told that they would experience physiological arousal. After the injections, subjects were placed in different situations—a happy one or an angry one. Those subjects in the happy situation often reported feeling happy, and their observable behaviors were smiles. However, those in the angry situation often reported feeling angry, and their observable behaviors were angry facial expressions. Schachter and Singer explained that subjects did not know that their physiological arousal was caused by hormone injections and they looked around for other causes in their environment. Subjects interpreted environmental cues, such as being in a happy or angry situation, as the cause of their arousal and thus reported feeling happy or angry. The Schachter-Singer cognitive theory was the first to show that cognitive factors, such as your interpretation of events, could influence emotional feelings.



1. Injection of hormone causes physiological arousal (rise in heart rate, etc.).

2. Explain physiological arousal by using situational cues.

3. Depending on situation, feel different emotions (happy or angry).

4. Show observable behaviors that match emotions.

The Schachter-Singer finding that your cognitive processes, such as thoughts, interpretations, and appraisals of situations, can trigger emotions became the basis for today's cognitive appraisal theory of emotions.

Cognitive Appraisal Theory

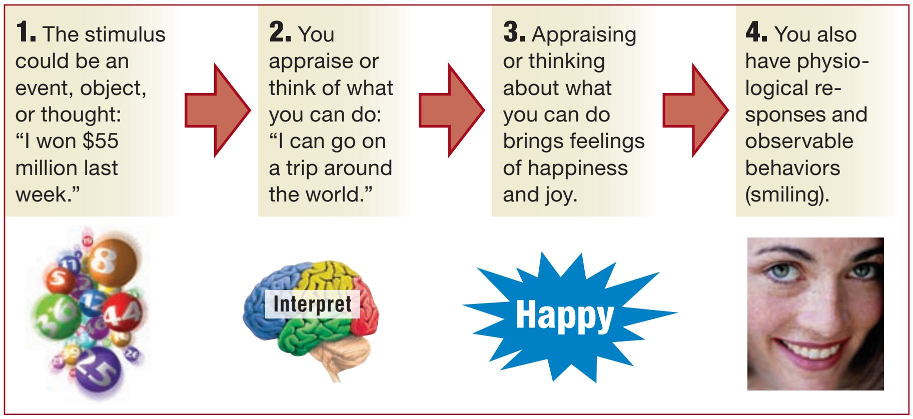
The cognitive appraisal theory began with the experiment of Schachter and Singer and developed into its present form because of many researchers (Ellsworth & Scherer, 2003; Lazarus, 2006).

The ***cognitive appraisal theory*** says that your interpretation or appraisal or thought or memory of a situation, object, or event can contribute to, or result in, your experiencing different emotional states.

Suppose you're thinking about having won the lottery last week and planning what to do with all that money. According to the cognitive appraisal theory, the sequence for how thinking results in feeling happy is shown in the figure on the right.

Thought then emotion. Thinking of your first serious kiss can make you feel happy, while thinking of times you were jealous can make you sad or angry. In these cases, as well as in feeling pride, envy, or compassion, the thinking or appraisal occurs before the emotion (Lazarus, 2006).

Emotion without conscious thought. Imagine being on a nature walk, turning a corner, and seeing a huge snake on the path. In this case, the feeling of fear is instant, without conscious thought or appraisal; you don't have to think "that's a dangerous snake and I better be careful." On the next page, we'll discuss how seeing a snake can elicit fear instantaneously, before awareness or conscious thoughts can occur (Helmuth, 2003b; Zajonc, 1984). Thus, in some situations, such as those that involve personal relationships, problems at work, fond family memories, or terrible tragedies, thoughts precede and result in emotional feelings. In other situations, such as those involving attack or threat to one's personal survival, emotions can occur instantly, without conscious thought or awareness.



1. The stimulus could be an event, object, or thought: "I won $55 million last week."

2. You appraise or think of what you can do: "I can go on a trip around the world."

3. Appraising or thinking about what you can do brings feelings of happiness and joy.

4. You also have physiological responses and observable behaviors (smiling).

The relatively new finding that certain emotions, especially fear, can occur without conscious thought or awareness brings us to the most recent approach to the study of emotions, called affective neuroscience, which we'll discuss next.

C. Affective Neuroscience Approach

Four Qualities of Emotions

What emotion do you feel?

Seeing this ferocious wolf suddenly appear on your nature walk would cause instant fear. The ability of humans to sense and evaluate stimuli as being more or less desirable to their well-being is an important function of emotions, which have four unique qualities (R. J. Dolan, 2002).

How quickly would you react?

1st. Unlike most psychological states, emotions are felt and ***expressed in stereotypical facial expressions,*** such as showing a fearful expression (open mouth, raised eyebrows), and accompanied by ***distinctive physiological responses*** (fear is accompanied by a fast heart rate, quick shallow breathing, and sweaty palms).

2nd. Emotions are ***less controllable*** than we might like and may ***not respond to reason.*** For example, advising someone to "calm down" or "control your temper" may have little effect. In fact, some people may need to attend anger management programs to help them gain some rational self-control over their hot tempers.

3rd. Emotions have an enormous ***influence on many cognitive processes,*** such as making decisions, developing personal relationships, and selecting goals. One reason for this is that you essentially have two brains: an older primitive or animal brain, called the limbic system (p. 80), which regulates emotions, and a newer developed forebrain, which influences but doesn't completely control the limbic system. For example, well-known politicians, who intellectually know better, have gotten into trouble by engaging in illicit sexual activities, and some students, who intellectually know better, admit to doing badly in their freshman year and explain that they were emotionally immature.

4th. Some emotions are ***hard-wired in the brain.*** That's why babies don't have to learn how to cry to gain attention or express basic needs or learn how to smile to show happiness and form social bonds with their parents or caretakers.

Study of emotions. Recently, the study of emotions has become one of the hottest topics in neuroscience, which studies patients who have discrete brain lesions and psychiatric and neurological disorders. Neuroscientists use brain scanning or imaging techniques to identify structures and neural activities in the living brain. These studies contribute to the new affective neuroscience approach to understand mood and emotions (Panksepp, 2008).

The ***affective neuroscience approach*** studies the underlying neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to experiencing and expressing different emotional states.

The word *affective* suggests affect or emotion. The word *neuroscience* suggests research methods that involve studying patients with neurological disorders and using methods that involve brain scans or imaging to identify neural activity in the living brain.

Emotional Detector and Memorizer

Can you detect a snake quicker than a flower?

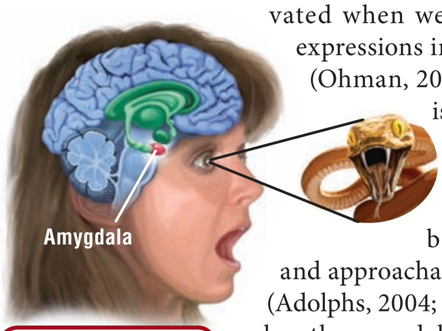
Detecting stimuli. If you were shown a number of stimuli, would you detect a snake quicker than a flower? For example, researchers found that, compared to detecting unemotional neutral targets (flowers, mushrooms), we are faster at detecting targets with emotional meaning, such as faces with positive (smiling) or negative (fearful) expressions, and threatening things, such as snakes or spiders. However, we are fastest at identifying emotional stimuli that may pose a threat—fearful faces, snakes (M. A. Williams & Mattingley, 2006). These findings support the idea that our brains have evolved the ability to quickly recognize dangerous things in our environment and thus increase our chances for survival. Further support for this idea comes from scanning or imaging studies (p. 70) that point to an emotional detector in the brain.

Threat to your survival

Emotional detector. Your physical survival depends in part on a brain structure about the size and shape of an almond—the amygdala (P. J. Whalen & Phelps, 2009).

The ***amygdala*** *(ah-MIG-duh-la)* is located in the tip of the brain's temporal lobe and receives input from all the senses. Using all this sensory input, the amygdala monitors and evaluates whether stimuli have positive (happy) or negative (fearful) emotional significance for our well-being and survival. It is also involved in storing memories that have emotional content.

One researcher said the amygdala (figure below) is like a guard dog that is constantly sniffing for threats, and this gives us an evolutionary advantage in terms of survival (LeDoux, 2003). For example, brain scans indicate the amygdala is especially activated when we view emotional facial expressions indicating fear or distress (Ohman, 2009). When the amygdala is damaged, patients often overlook important emotional cues. For instance, they identify all faces as being more trustworthy and approachable than the rest of us do (Adolphs, 2004; Dobbs, 2006a). Similarly, when the amygdala is damaged in animals, they no longer learn to fear and avoid dangerous situations (Hamann et al., 2002).



Amygdala is an emotional detector and memorizer.

Emotional memorizer. Besides being involved in evaluating positive and negative emotional stimuli, the amygdala is also involved in ***storing memories with emotional content*** (Phelps, 2004). The amygdala is the reason you can remember that a joke is funny or a face is happy or threatening. This means the amygdala is involved in both detecting emotional stimuli and remembering emotional content. How the amygdala detects a snake almost instantaneously is a neat trick.

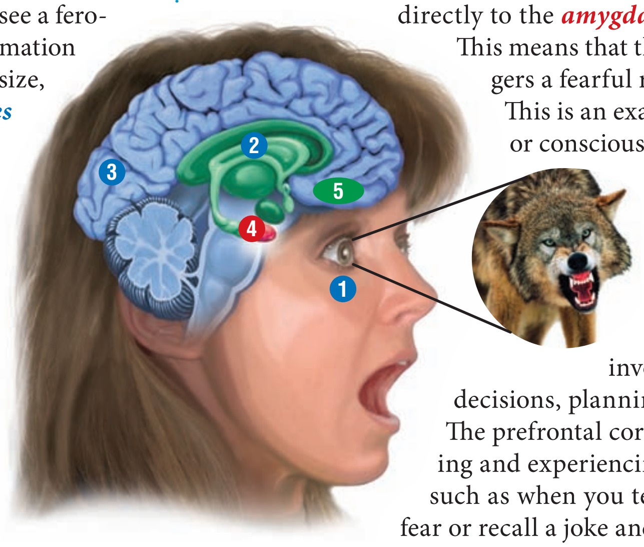
Brain Circuits for Emotions

What happens when you feel fear?

Researchers have used brain scanning or imaging techniques (fMRI—p. 70) to measure neural activity and trace neural pathways or circuits throughout the living brain. We'll focus on the neural activity that occurs when a person is confronted with a fearful stimulus, such as seeing a ferocious wolf. This neural circuit is important for our survival and has received considerable attention (Quirk, 2007; M. Siegal, 2005).

A. Slower Circuit

We'll give a simplified version of the sequence of neural activity in the brain that would occur when you see a ferocious wolf. Visual information about the wolf's shape, size, and color enters the ***eyes*** (1), which send neural information about the "wolf" to a structure in the brain called the ***thalamus*** (2). In turn, the thalamus relays the neural information to another part of the brain called the ***visual cortex*** (3). The visual cortex transforms the neural signals into the image of a ferocious wolf and relays the "wolf" information to the ***amygdala*** (4). The amygdala interprets the neural information and signals the presence of a threat, which results in feelings of fear, an associated fearful facial expression, and probably a lot of yelling and running to escape from the threat. And this neural activity happens very fast, in about 0.12 second. However, there is an even faster circuit that gives a quicker warning.



B. Faster Circuit

Researchers have evidence of an even faster circuit for identifying threatening stimuli. As usual, visual information about the wolf enters the ***eyes*** (1), which send neural information about the "wolf" to the ***thalamus*** (2). The thalamus sends neural information directly to the ***amygdala*** (4), saving time by skipping the ***visual cortex*** (3). This means that the amygdala recognizes the threatening wolf and triggers a fearful response almost instantaneously after seeing the wolf. This is an example of an emotion occurring without any awareness or conscious thought.

Researchers believe that this **faster circuit** evolved because its amazingly quick warning of a threatening stimulus greatly improves our chances of avoiding and surviving dangerous stimuli.

C. Prefrontal Cortex

The part of your brain that is involved in complex cognitive functions, such as making decisions, planning, and reasoning, is called the ***prefrontal cortex*** (5). The prefrontal cortex has several functions: It is involved in remembering and experiencing emotions even when the fear object is not present, such as when you tell a friend about your wolf encounter and again feel fear or recall a joke and laugh; it is also involved in anticipating and analyzing the potential rewards, punishments, and emotional consequences of performing or not performing certain behaviors (Fuster, 2008). For example, the prefrontal cortex is involved in analyzing the emotional consequences, rewards, and punishments of deciding whether to go to a party instead of studying for an exam. Because reason often has less effect on emotions than you would like, you may decide to go and enjoy the party and live with the potential disappointment and unhappiness of doing poorly on the exam.

In some cases, faulty functioning of the prefrontal cortex, perhaps due to undeveloped neural connections or circuits, may result in less rational control of emotions, which in turn increases the risk for committing impulsive acts of violence or aggression (Strueber et al., 2006). Researchers warn that this finding points to the need for developing new treatments, both behavioral and drug, to help some people suppress their impulsive and violent emotions (Bradley et al., 2005; Quirk, 2007).

The kinds of studies that we have just discussed illustrate the affective neuroscience approach to understanding emotions as well as emotional disorders.

Fear and the Amygdala

Why do some have more fears?

Some individuals suffer from social phobias, which means they avoid going out in public because they have an enormous fear of being scrutinized, which would surely result in being humiliated or embarrassed. Researchers wondered if these fears might be reflected in the activity of the amygdala, which evaluates and signals threats from the environment.

Individuals with social phobias and healthy individuals were shown color photos of faces (happy, fearful, angry, and contemptuous) while researchers used brain scans (fMRIs) to record the neural activity of the amygdala. When individuals with social phobia were looking at photos of angry and contemptuous faces, there was increased neural activity in the left amygdala compared to the activity in healthy individuals. Researchers concluded that the amygdala of social phobics is particularly active when processing angry and contemptuous faces (M. B. Stein et al., 2002). This study, which is an example of the affective neuroscience approach, identified neurological factors that may be useful in evaluating and treating emotional disorders.

Phobias and other anxieties are believed to result from there being more neural connections running from the amygdala to the cortex (p. 74) than from the cortex to the amygdala. This explains why our anxieties often control our thoughts and why our thoughts cannot always lower our anxieties (Dobbs, 2006a).

Social fears result in an overactive amygdala.

Photo Credit: left, © Photo24/Brand X Pictures/Getty Images

D. Universal Facial Expressions

Definition

When did you first smile?

When you were about 4–6 weeks old, you began to smile, which greatly pleased your parents. Smiling is considered one of the universal emotional expressions (Ekman, 2003).

Universal emotional expressions are specific inherited facial patterns or expressions that signal specific feelings or emotional states, such as a smile signaling a happy state.

For example, notice that although the four individuals in the photos come from four different countries, they display similar facial expressions—smiles—which you would interpret as showing happiness.

Why do people from different cultures smile the same way?

Number of expressions. Researchers generally agree that seven facial expressions for emotions are universal, which means they are recognized across cultures: anger, happiness, fear, surprise, disgust, sadness, and contempt (Ekman, 2003; Ekman & Rosenberg, 2005). Other emotions, such as pride, jealousy, and compassion, do not have particular facial expressions.

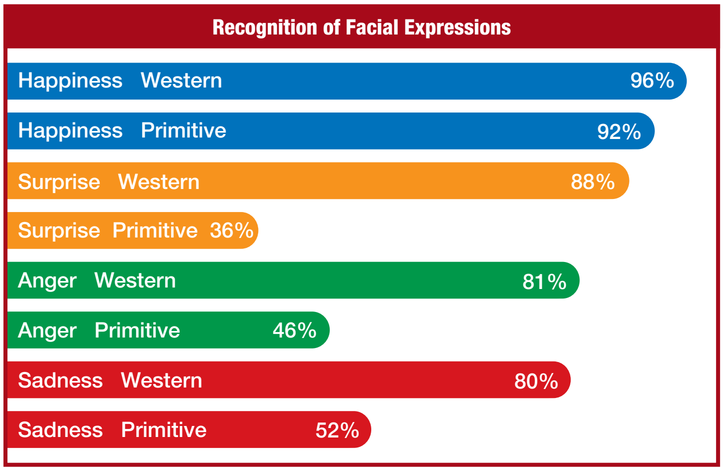
The existence of universal emotions was scientifically formulated by Charles Darwin (1872/1965), and his ideas have inspired modern-day researchers to study universal emotional expressions (Ekman, 2003). We'll review two kinds of evidence—cross-cultural and genetic—that support the idea of universal emotional expressions.

Cross-Cultural Evidence

How do individuals from relatively isolated cultures in New Guinea, Burma, Thailand, and Borneo (photos from top to bottom) know how to smile or what a smile means? One answer is that a smile is one of the unlearned, inherited universal emotional expressions. For example, researchers showed photos of different facial expressions to individuals in 20 different Western cultures and 11 different primitive (illiterate and isolated) cultures. As the graph below indicates, researchers found that individuals in both Western and primitive cultures showed significant agreement on which facial expressions signaled which emotions. Most individuals in Western and primitive cultures agreed that a smile indicated happiness. However, only about one-third of individuals in primitive cultures agreed that an open-mouth and raised-eyebrows expression indicated surprise.

Based on the cross-cultural findings shown in the graph below, researchers concluded that there are innately or biologically determined universal facial expressions for emotions. Universal emotional expressions are thought to have evolved because they served adaptive and survival functions for our ancestors (Ekman, 2003; Ekman & Rosenberg, 2005).

Support for universal emotional expressions also comes from genetic evidence.



Genetic Evidence

How does an infant who is born blind learn to smile? Is it possible that the programming of specific facial expressions, such as smiling, is in the DNA, which is a chemically coded alphabet that contains and writes out genetic instructions for the development of the body and brain? One answer to this question comes from observing the development of emotional expressions in infants.

Researchers found that at 4–6 weeks of age, infants begin to smile. The question is whether an infant's smiling is biologically programmed or whether the infant has learned to smile by observing and imitating the parents' facial expressions. The answer is that even infants born blind, who never observe their parents smiling, begin to smile at 4–6 weeks. This observation supports the idea that some facial expressions, such as smiling, are biologically programmed (Eibl-Eibesfeldt, 1973).

Additional evidence for universal emotions comes from reports that infants in all cultures develop facial expressions in a predictable order. For instance, newborns show facial expressions signaling disgust or distress in response to foul tastes or odors, infants 4–6 weeks old begin to smile, infants 3–4 months old show angry and sad facial expressions, and infants 5–7 months old show fear (Izard, 1993; Kopp & Neufeld, 2003).

More recent research examining the facial expressions of sighted and blind individuals found that blind individuals produced the same facial expressions for anger, disgust, surprise, joy, sadness, and contempt as those who are sighted. These results indicate that facial expressions are innate or genetically programmed and not learned through observation (Matsumoto & Willingham, 2009).

Researchers conclude that evidence from cross-cultural studies on facial expressions, the development of emotional expressions in infants, and the shared facial expressions among sighted and blind individuals indicate strong biological (genetic) influences on the development of emotional expressions. But why should humans have an innate genetic program for the development of facial emotional expressions? There are several interesting answers to this question.

E. Functions of Emotions

What good are emotions?

To appreciate the value and worth of emotions, try living a single day without feeling or expressing any emotions. It would be one of the worst days of your life because emotions have three important functions. Emotions send powerful ***social signals*** about how you feel; emotions help you ***adapt and survive*** in your world; and emotions ***arouse and motivate*** many of your behaviors. We'll examine each emotional function in turn.

Social Signals

This baby's facial expression is a signal to show others that she is ________.

You would probably fill in the above blank with "distressed, unhappy, in need of something (food, dry diaper)." Thus, one function of emotions is to ***send social signals*** about one's feelings or needs. Because the baby's facial expression signals distress, she is likely to elicit help, sympathy, or compassion from her parents or caregiver. This is one example of how we send signals through facial expressions (Keltner et al., 2003).

Facial expressions that accompany emotions may send social signals about how we feel as well as provide social signals about what we are going to do.

For example, if you smiled at a classmate you didn't know, it may signal you're feeling friendly and perhaps that you wish to meet this person.

In some cases, there may be gender differences in the ability to recognize facial expressions. For instance, men appear to be better than woman at finding angry faces in a crowd, and women appear to be better than men in detecting facial expressions signaling happiness, sadness, surprise, and disgust (M. A. Williams & Mattingley, 2006).

Survival, Attention & Memory

If you're walking through a strange neighborhood at night, you may feel fear. Fear is a signal that all is not well, so you should be careful. Emotions help us evaluate situations (Rothbart & Sheese, 2007).

The ***evolutionary theory of emotions*** says that one function of emotions is to help us evaluate objects, people, and situations in terms of how good or bad they are for our well-being and survival (Rozin, 2003).

There are many examples of emotions having ***survival value:*** showing anger (below photo) to escape or survive a dangerous or threatening situation, showing disgust to signal the presence of poisonous or rotten food, or feeling fear and becoming watchful when walking home at night.

This woman's facial expression is a signal to show that she is ________, which may help her survive ________ situations.

Our facial expressions also help us manage our sensory experiences. For instance, when we express disgust, we block our nasal passages, narrow our visual field, and slow our eye movement. This helps us to not smell or see disgusting things. When we express fear, we open our nasal passages, enlarge our visual field, and quicken our eye movements, which helps us to be more aware of our surroundings (Susskind et al., 2008). Emotions also affect our attention and memory.

Attention. Feeling happy when you see your honey means he or she will get your full attention. Feeling angry when you are threatened means you're totally focused on getting out of this situation. These are examples of another function of emotions, which is to ***focus one's attention*** and thus better detect and respond to emotional situations (Rothbart & Sheese, 2007).

Memory. Strong emotions trigger hormone secretion that causes memories to be "written in stone" (p. 247). Thus, emotions help ***increase memory*** of emotionally charged events (Dobbs, 2006a). This results in better remembering events that are beneficial or dangerous to our well-being.

Arousal and Motivation

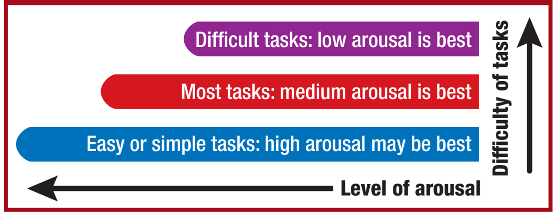
Earlier we discussed how Bethany's emotional reaction to seeing a shark included a variety of physiological responses, such as heart pounding and adrenaline pumping, that cause arousal. One major function of emotions is to ***produce general arousal,*** which prepares the body for some action (Hamm et al., 2003). In Bethany's case, maximum arousal helped her get to shore, but in other cases, such as taking a test, maximum arousal may interfere with performance.

In fact, there is a relationship between emotional arousal and performance on a task. That relationship is called the Yerkes-Dodson law.

The ***Yerkes-Dodson law*** says that performance on a task is an interaction between the level of physiological arousal and the difficulty of the task. For difficult tasks, low arousal results in better performance; for most tasks, moderate arousal helps performance; and for easy tasks, high arousal may facilitate performance.

If we apply the Yerkes-Dodson law to taking difficult exams, we would predict that a person with high test anxiety (high arousal) would do more poorly than someone with comparable ability but low test anxiety. Researchers confirmed this prediction by finding that students who were highly aroused because of either high test anxiety or much coffee (caffeine) scored more poorly on difficult tests than students who had low test anxiety or were less aroused (less caffeine) (K. J. Anderson, 1994). The graph below shows how the optimum level of arousal for best performance depends on the complexity of the task.

Yerkes-Dodson Law: Interaction of Task and Arousal



Difficult tasks: low arousal is best
Most tasks: medium arousal is best
Easy or simple tasks: high arousal may be best
Difficulty of tasks
Level of arousal

Besides affecting performance on various tasks, emotions also increase physiological arousal, which forms the basis for lie detector tests, discussed in the Application section (pp. 370–371).

Next, we turn to a positive emotion and the question: Why doesn't happiness last longer?

F. Happiness

Positive Emotions

What makes you happy?

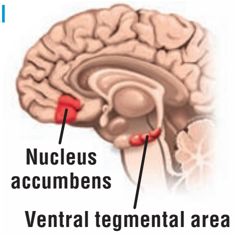
Pam was unmarried, eight months pregnant, and holding down two jobs when she stopped in at Jackson's Food Store for her morning orange juice and one lottery ticket. She remembers praying, "Please, God, let something happen so I can afford a small studio apartment" (S. Reed & Free, 1995, p. 63). The next day she was ecstatic when she discovered that her single lottery ticket was worth $87 million (left photo).

I won 87 million dollars!

Happiness, usually indicated by smiling and laughing, can result from momentary pleasures, such as a funny commercial; short-term joys, such as a great date; and long-term satisfaction, such as an enjoyable relationship.

Inside the brain, the amygdala is involved in recognizing happy facial expressions and remembering happy occurrences (laughing at jokes) (W. M. Kelley, 2002; P. J. Whalen et al., 2009). In addition, the brain has a special reward/pleasure center that's involved in happiness.

The ***reward/pleasure center*** includes several areas, such as the nucleus accumbens and ventral tegmental area, and several neurotransmitters, especially dopamine. These and other brain areas make up a neural circuit that produces rewarding and pleasurable feelings, such as happiness.



Reward/pleasure center

Researchers found that many behaviors—eating, developing romantic attachments, engaging in sex, gambling, using recreational drugs (cocaine), looking at photos of attractive people, and listening to great music—activate the brain's reward/pleasure center (right figure) and result in happy and pleasurable feelings (Berridge, 2003; Nestler, 2005).

For example, the $87-million check that Pam received activated her brain's reward/pleasure center to trigger much happiness, and this occurrence was stored as a happy memory by her amygdala. But, happiness is about more than measurable physiological processes; it is also about people's life experiences. Researchers have asked: What makes people happy in the long term?

Long-Term Happiness

How much happiness can money buy?

When researchers interviewed lottery winners 1 to 24 months after they had won large sums of money, the majority reported positive changes, such as financial security, new possessions, more leisure time, and earlier retirement. However, when asked to rate their happiness one year after winning, lottery winners were no happier than before (Diener & Diener, 1996). Why the happy feeling of winning a lottery doesn't last is explained by the adaptation level theory.

The ***adaptation level theory*** says that we quickly become accustomed to receiving some good fortune (money, job, car, degree); we take the good fortune for granted within a short period of time; and as a result, the initial impact of our good fortune fades and contributes less to our long-term level of happiness.

According to the adaptation level theory, the immediate emotional high of obtaining good fortune—such as graduating from college, getting married, buying a new car, getting a much-wanted job, or winning a lottery—will fade with time and contributes less and less to our long-term happiness (Brickman et al., 1978; Easterlin, 2003; Seligman, 2002). For example, three weeks after winning $87 million, Pam gave birth to Nicholas, and she said, "Winning the lottery was pretty exciting, but it can't compare to Nicholas. I want him to grow up caring about people and knowing the value of work" (S. Reed & Free, 1995, p. 64).

Long-term happiness. Researchers find that happiness is not a fixed state and does not primarily result from getting more money, cars, clothes, or promotions because these achievements gradually lose their emotional appeal, as predicted by the adaptation level theory. Rather, being happy is a continuous process associated with making an effort to enjoy simple, daily pleasurable events, people, or situations. It includes a daily diet of little highs as well as pursuing personal goals, developing a sense of meaningfulness, having intimate relationships, and not judging yourself against what others do but by your own yardstick (Lykken, 2003; Seligman, 2002).

Pam said, "Winning the lottery was great, but it can't compare to my baby."

Gender differences in happiness. Researchers report that women are, on average, happier than men in early adulthood, but men end up happier later in life. The point at which men's happiness exceeds that of women is near the age of 50. One explanation is that by age 50, men are more satisfied with two major aspects of their lives: family (men are more likely to be married than women after age 34) and finances (men have greater spending power) (Plagnol & Easterlin, 2008).

Genetic differences in happiness. One reason some people are just generally happier than others is one's individual ***happiness set point.*** Each person has a set point for experiencing a certain level of happiness—some more and some less. Although happiness can go up or down, it generally returns to the person's set point. Researchers estimate that one's personal level for being happy is set half by inherited or genetic influences, which affect the development of helpful or hurtful cognitive and personality traits, and half by various environmental factors, such as one's career, relationships, and finances (Lykken, 2003).

Riches don't guarantee happiness.

Although emotional feelings are common to all people, you'll see next that displays of emotional expressions differ across cultures.

G. Cultural Diversity: Emotions across Cultures

Showing Emotions

Do you cover your mouth when you laugh?

When I (R.P.) visited Japan, I noticed the Japanese covered their mouths when laughing, something we Americans never do. This Japanese–American cultural difference comes from differences in emotional display rules (Ekman, 2003, 2007).

Display rules are specific cultural norms or rules that regulate how, when, and where a person expresses emotions and how much emotional expression is appropriate.

Americans **don't cover** their mouths when they laugh.

Here are examples of how different cultures have developed different display rules for emotional expressions.

Laughing and crying. American display rules generally encourage public displays of emotions, such as open-mouth laughing. In contrast, Japanese display rules for laughing include covering one's open mouth because showing much emotion in public is discouraged (Matsumoto et al., 2002). An Inuit (Eskimo) mother may let a baby cry to send the message that her culture disapproves of the display of negative emotions (Mauss, 2005).

Smiling. Another common public display of emotion made by Americans is smiling. In contrast, Russians rarely smile in public. Does this mean Russians are less happy than Americans? Not necessarily. Russians are more likely to display their emotions in private gatherings, such as with family, but in public situations Russians control their emotions more than Americans. Interestingly, Americans may mistake the restricted emotions displayed by Russians for irritability or unhappiness, and Russians may mistake the big smiles displayed by Americans as being phony (Krakovsky, 2009).

Japanese **cover** their mouths when they laugh.

Display rules can also differ within a culture. For example, American adolescent girls and women smile more than boys and men do, and women are better than men at interpreting nonverbal cues (facial expressions, such as smiling, and body gestures) (LaFrance et al., 2003).

Anger. Among the Inuit (Eskimos), feelings of anger are strongly condemned, but among certain Arab groups, a man's failure to respond with anger is seen as dishonorable (Abu-Lughod, 1986; Briggs, 1970).

These examples show how different cultures have developed different display rules for emotional expressions. One may be unaware of such display rules until visiting another culture (Marsh et al., 2003).

Potential problems. Because of different display rules for expressing emotions, people from one culture may run into problems when traveling or conducting business in another culture. For example, Westerners often make direct eye contact and may show emotions during business meetings, while Asians avoid direct eye contact and outward expressions of emotions. Because of increased international travel and business, there are now companies that give advice and training on dealing with the display rules of other cultures (www.communicaid.com).

These examples show how culture influences the expression of emotional display rules. Depending on your culture, you also rate different emotions as being more or less intense.

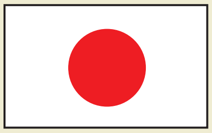
Perceiving Emotions

What's the most intense emotion?

Of these five emotions—surprise, anger, happiness, disgust, and sadness—which one do you rate as the most intense?

____

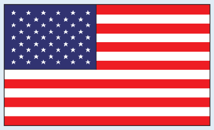
It turns out your rating depends very much on your culture. For example, because the Japanese have a long history of discouraging any show of emotional intensity in public, researchers guessed that their ratings of emotional intensity would be different from those of Americans, who have a history of showing emotions of all intensities in public (Reitman, 1999).



Japanese rated ***disgust*** as the most intense of five emotions.

Disgust

Researchers asked a group of Japanese and a group of Americans to look at photos of five emotional expressions—anger, surprise, happiness, disgust, and sadness—and rate the intensity of each. As predicted, the Japanese gave lower ratings of ***emotional intensity*** to all five emotional expressions than the Americans did. The Japanese rated disgust as the most intense emotion of the five, while the Americans rated happiness as the most intense (Matsumoto & Ekman, 1989). This study illustrates how cultures affect the display of emotions and our perception of an emotion's intensity (Rozin, 2003).



Americans rated ***happiness*** as the most intense of five emotions.

Happiness

A recent study finds that perceiving emotions in music may be a universal human ability. Cameroon's Mafa farmers and Westerners are from vastly different cultures, yet they perceive emotions in music similarly. Both groups perceive fast-paced pieces as happy and slow-paced pieces as fearful. Also, they generally agree on which passages are sad (B. Bower, 2009a; T. Fritz, 2009).

Next, we'll discuss emotional intelligence.

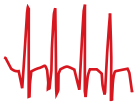
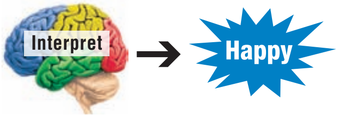
Concept Review

1. An emotion is defined in terms of four components: You interpret or (a) ________ some stimulus, thought, or event in terms of your well-being; you have a subjective (b) ________, such as being happy or fearful; you experience bodily responses, such as increased heart rate and breathing, which are called (c) ________ responses; and you often show (d) ________ behaviors, such as crying or smiling.



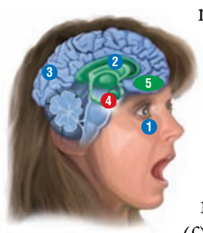
2. A peripheral theory says that emotions result from specific physiological changes in our bodies and that each emotion has a different physiological pattern. This theory, which says that we feel fear because we run, is called the ________ theory.

3. Another peripheral theory says that feedback from the movement of facial muscles and skin is interpreted by your brain as an emotion; this theory is called the (a) ________ theory. Although emotions can occur without feedback from facial muscles, facial feedback can influence your mood and contribute to the (b) ________ of an emotion.



4. A theory of emotions that grew out of the work of Schachter and Singer says that your interpretation, appraisal, thought, or memory of a situation, object, or event can contribute to, or result in, your experiencing different emotional states. This is called the ________ theory.

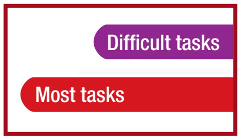
5. The most recent approach to understanding emotions studies the neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to our experiencing and expressing different emotional states. This is called the ________ approach.



6. Emotions have four qualities: They are expressed in stereotypical (a) ________ expressions and have distinctive (b) ________ responses; they are less controllable and may not respond to (c) ________; they influence many (d) ________ functions; and some emotions, such as smiling, are (e) ________ in the brain. The brain area that functions to detect and evaluate stimuli, especially threatening ones, and to store memories with emotional content is called the (f) ________. Because this brain structure receives sensory information so quickly, it triggers a fearful reaction without (g) ________. The brain structure involved in producing emotions from thoughts alone and in analyzing the emotional consequences of actions is called the (h) ________.

7. Specific inherited facial patterns or expressions that signal specific feelings or emotional states across cultures, such as a smile signaling a happy state, are called (a) ________. These emotional expressions, which include anger, happiness, fear, surprise, disgust, sadness, and contempt, are thought to have evolved because they had important (b) ________ and ________ functions for our ancestors.

8. According to one theory, we inherit the neural structure and physiology to express and experience emotions, and we evolved basic emotional patterns to adapt to and solve problems important for our survival; this is called the (a) ________ theory. Facial expressions that accompany emotions send signals about how one (b) ________ and what one intends to do. Emotions focus one's (c) ________ so one can better respond to emotional situations and also increases (d) ________ of situations that may be either beneficial or dangerous to one's well-being.



9. Your performance on a task depends on the amount of physiological arousal and the difficulty of the task. For many tasks, moderate arousal helps performance; for new or difficult tasks, low arousal is better; and for easy or well-learned tasks, high arousal may facilitate performance. This relationship between arousal and performance is known as the ________.

10. According to one theory, you soon become accustomed to big happy events, such as getting a car; this theory is called the (a) ________. Long-term happiness is less dependent on wealth and more dependent on pursuing your own personal (b) ________ and developing meaningful (c) ________. Some people are just generally happier and some are generally less happy because of their happiness (d) ________.

11. Specific cultural norms that regulate when, where, and how much emotion we should or should not express in different situations are called ________. These rules explain why emotional expressions and intensity of emotions differ across cultures.

Answers: *1. (a) appraise, (b) feeling, (c) physiological, (d) observable; 2. James-Lange; 3. (a) facial feedback, (b) intensity; 4. cognitive appraisal; 5. affective neuroscience; 6. (a) facial, (b) physiological, (c) reason, (d) cognitive, (e) hard-wired, (f) amygdala, (g) awareness or conscious thought, (h) prefrontal cortex; 7. (a) universal facial expressions, (b) adaptive, survival; 8. (a) evolutionary, (b) feels, (c) attention, (d) memory, recall; 9. Yerkes-Dodson law; 10. (a) adaptation level theory, (b) goals, (c) relationships, (d) set point; 11. display rules*

H. Research Focus: Emotional Intelligence

What Is Emotional Intelligence?

What is it and who has it?

One of the exciting things about being a researcher is the chance to come up with new ideas. This happened in the early 1990s, when researchers came up with the idea of emotional intelligence, which they suggested made people more effective in social situations (Salovey & Mayer, 1990). By the mid-1990s, popular magazines, such as *Time,* declared that emotional intelligence may redefine what it means to be smart and may be the best predictor of success in life (Gibbs, 1995).

Emotional intelligence is the ability to perceive emotions accurately, to take feelings into account when reasoning, to understand emotions, and to regulate or manage emotions in oneself and others (Salovey et al., 2008).

Is emotional intelligence the key to Oprah's success?

Unlike the traditional idea of intelligence involving performance on cognitive tests (IQ scores—p. 282), emotional intelligence involves how well people perceive, express, and regulate emotions in themselves and others. The author of the book *Emotional Intelligence* (Goleman, 1995, 2005) said in an interview, "Oprah Winfrey's ability to read people and identify with them is at the heart of her success" (S. A. Brown, 1996, p. 85). In other words, the reason for Oprah's incredible success as a talk-show host is that she rates very high in emotional intelligence.

Since the early 1990s, researchers have been working to better understand emotional intelligence and just how important it really is (Mayer et al., 2008).

How Important Is Emotional Intelligence?

All agree that emotions play important roles in our lives.

Here are some common remarks that show how emotions can influence our behaviors.

- "I was so angry, I couldn't think straight."
- "I get worse when people tell me to calm down."
- "When we argue, I get mad and say the wrong thing."
- "Sometimes I act on my feelings, right or wrong."

These kinds of self-reports point to the influence that emotions can have on what we say and do and on our success in life. According to supporters of emotional intelligence, the better our understanding of how emotions work, the more likely we are to find a compromise between our often strong emotional feelings ("I felt like doing that") and our equally strong rational thoughts ("I knew I should not have done that") (Mayer et al., 2000). However, these kinds of self-reports need to be confirmed by a more scientific technique, such as using a valid and reliable emotional intelligence test. Emotional intelligence tests continue to be developed, and additional tests of reliability and validity (p. 287) are necessary. Thus, the findings below are considered preliminary.

Preliminary findings. Here are some findings reported from recent tests to measure emotional intelligence: Youths who scored higher on emotional intelligence tests were less likely to have smoked cigarettes; schoolchildren who scored higher were rated as less aggressive by their peers and more helpful by their teachers; college-age males who scored higher were less likely to use alcohol and other drugs; and higher scores were related to being more empathetic and satisfied with life (Brackett et al., 2004; Lopes et al., 2003; Salovey & Pizarro, 2003).

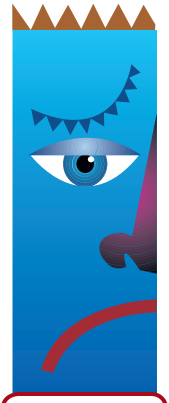
Emotional intelligence is also important in romantic relationships. A study with college-age couples found that the unhappiest couples were those in which both individuals had low emotional intelligence test scores and the happiest couples were those in which both individuals scored high on the same test. Couples in which only one partner scored high on emotional intelligence, on average, fell between the other groups in terms of happiness (Brackett et al., 2005).

Researchers are only recently beginning to understand how it is that we can perceive, express, and regulate emotions (A. Underwood, 2006). Next, we'll learn about how we perceive emotional expressions.

How Do We Perceive Emotional Expressions?

Scientists have known that we are able to detect emotions, such as fear and happiness, in people's faces almost instantly (M. A. Williams & Mattingley, 2006). Researchers now understand the brain mechanisms that permit us to very easily perceive emotions in others.

We are able to share the emotions others feel because of mirror neurons, which track the emotions of the person we are with and replicate the same emotions in us by activating our brains in the same way the other person's brain is activated (Goleman, 2006b). The discovery of mirror neurons shows us that human brains are innately prepared to connect with others in an intimate way, which enables us to share the emotions of others and be sensitive to their feelings.



Mirror neurons help us perceive emotions in others.

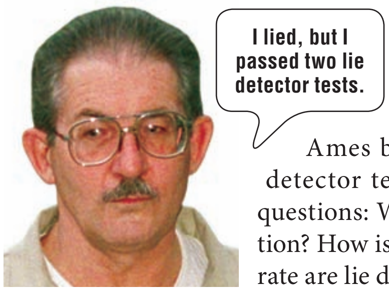
When we empathize with someone, the activation pattern in our brains becomes the same as that of the person we are empathizing with (Goleman, 2006a). For instance, by using fMRI scans (p. 70), researchers found that feeling disgust activates similar parts of the brain when people smell a disgusting odor and when they observe a video of someone else feeling disgusted (Rizzolatti et al., 2006). Interestingly, people who score higher on empathy tests exhibit stronger mirror neuron reactions to others' facial expressions. Also, it appears that children with autism have mirror neuron deficiencies, which may explain why they are unable to perceive the emotional expressions of others (Binkofski & Buccino, 2007; Keysers, 2007).

Next, we'll learn about how difficult it is to accurately detect whether someone is lying.

Photo Credit: © Carlo Allegri/Getty Images

I. Application: Lie Detection

How did a spy pass a lie detector test twice?



I lied, but I passed two lie detector tests.

For nine years, the Russians paid or promised $4.6 million to Aldrich Ames (photo on right), who was a high-level Central Intelligence Agency official. Later, Ames pleaded guilty to espionage, which involved selling secrets to the Russians. Ames is currently serving a life sentence in prison. The Ames case brings up the issue of lie detection because he reportedly passed at least two lie detector (polygraph) tests during the time that he was selling U.S. secrets to Russia (R. L. Jackson, 1994). The publicity surrounding this case made people ask, "How could Ames be selling secrets and pass two lie detector tests?" The Ames case raises three questions: What is the theory behind lie detection? How is a lie detector test given? How accurate are lie detector tests?

What Is the Theory?

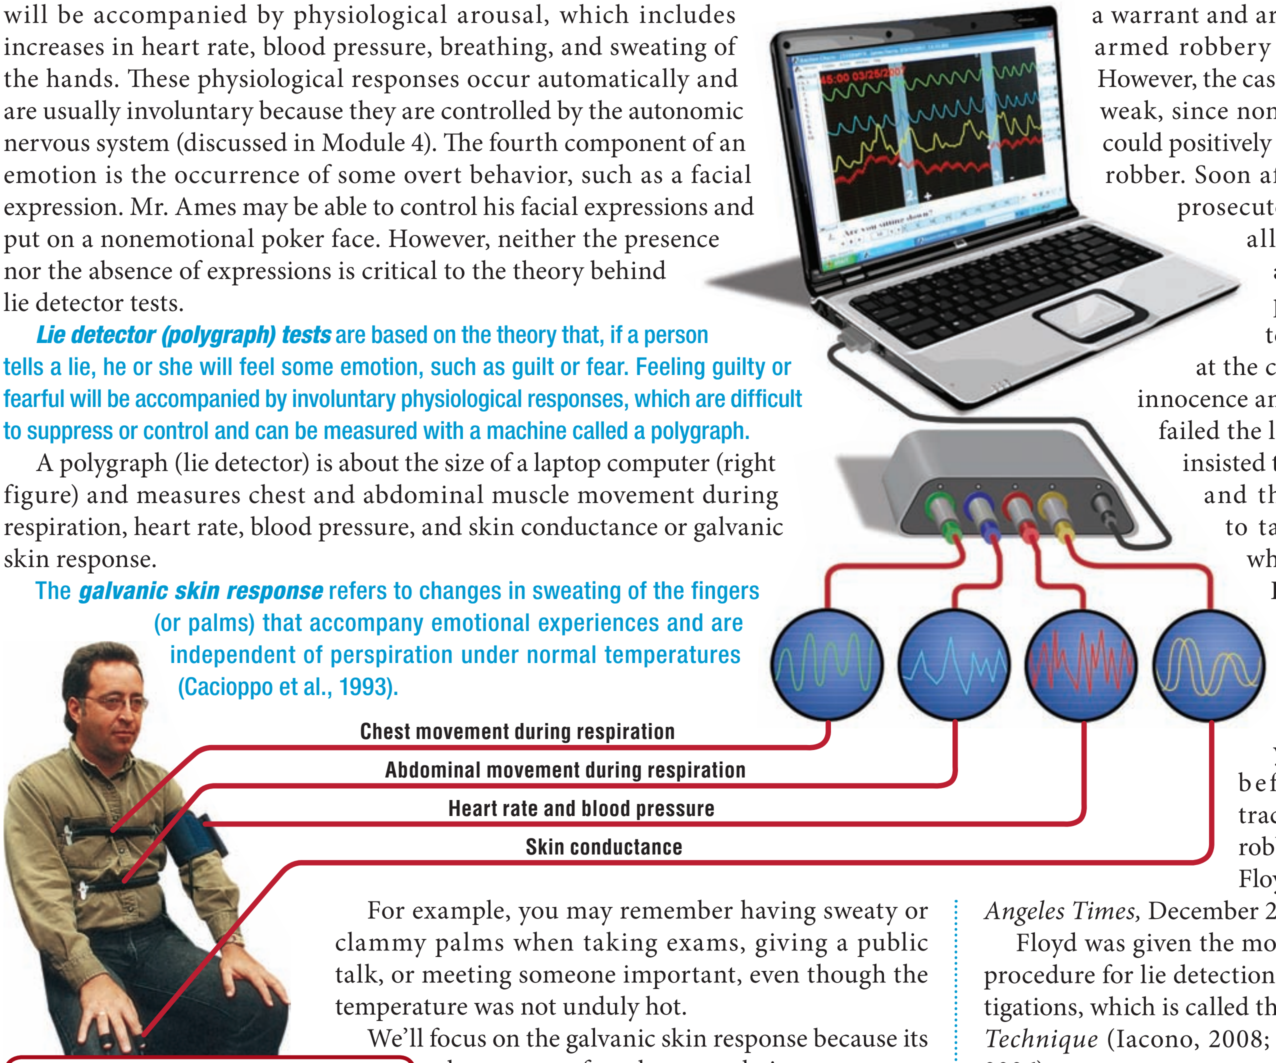
Does the test measure lying?

The lie detector test is based on the four components of an emotion that we discussed earlier. The first component of an emotion is interpreting or appraising a stimulus. In this case, Ames will need to interpret questions such as "Have you ever sold secrets to Russia?" The second component of an emotion is a subjective feeling, such as whether Ames will feel any guilt or fear when he answers "Yes" or "No" to the question "Have you ever sold secrets to Russia?" The third component of an emotion is the occurrence of various physiological responses (figure below). If Mr. Ames feels guilty about selling secrets, then his guilt feeling will be accompanied by physiological arousal, which includes increases in heart rate, blood pressure, breathing, and sweating of the hands. These physiological responses occur automatically and are usually involuntary because they are controlled by the autonomic nervous system (discussed in Module 4). The fourth component of an emotion is the occurrence of some overt behavior, such as a facial expression. Mr. Ames may be able to control his facial expressions and put on a nonemotional poker face. However, neither the presence nor the absence of expressions is critical to the theory behind lie detector tests.

Lie detector (polygraph) tests are based on the theory that, if a person tells a lie, he or she will feel some emotion, such as guilt or fear. Feeling guilty or fearful will be accompanied by involuntary physiological responses, which are difficult to suppress or control and can be measured with a machine called a polygraph.

A polygraph (lie detector) is about the size of a laptop computer (right figure) and measures chest and abdominal muscle movement during respiration, heart rate, blood pressure, and skin conductance or galvanic skin response.

The ***galvanic skin response*** refers to changes in sweating of the fingers (or palms) that accompany emotional experiences and are independent of perspiration under normal temperatures (Cacioppo et al., 1993).



Chest movement during respiration
Abdominal movement during respiration
Heart rate and blood pressure
Skin conductance

Man hooked up to lie detector (polygraph)

For example, you may remember having sweaty or clammy palms when taking exams, giving a public talk, or meeting someone important, even though the temperature was not unduly hot.

We'll focus on the galvanic skin response because its changes are often the most obvious.

What Is a Lie Detector Test?

Is the suspect lying?

Very few details have been released about how Mr. Ames, who apparently lied, passed two lie detector tests. Instead, we'll use a more detailed report of a man named Floyd, who told the truth but failed two lie detector tests.

Floyd was very surprised when two police officers came to his home. They had a warrant and arrested him for the armed robbery of a liquor store. However, the case against Floyd was weak, since none of the witnesses could positively identify him as the robber. Soon after his arrest, the prosecutor offered to drop all charges if Floyd agreed to take, and pass, a lie detector test. Floyd jumped at the chance to prove his innocence and took the test. He failed the lie detector test but insisted that he had not lied and that he be allowed to take a second one, which he also failed. Eventually Floyd was tried, found guilty, and sent to prison. He served several years behind bars before his lawyer tracked down the real robbers, which proved Floyd's innocence (*Los Angeles Times,* December 22, 1980).

Floyd was given the most commonly used procedure for lie detection in criminal investigations, which is called the *Control Question Technique* (Iacono, 2008; Iacono & Patrick, 2006).

Photo Credits: top, © Getty Images; bottom left, Photograph by Joel Reicherter, reprinted by permission

Reprinted by permission of the illustrator. All rights reserved.

The ***Control Question Technique*** refers to a lie detection procedure in which the examiner asks two kinds of questions: neutral questions that elicit little emotional response, and critical questions that are designed to elicit large emotional responses. The person answers only "Yes" or "No" to the questions and, if guilty, is expected to show a greater emotional response to the critical questions than to the neutral questions.

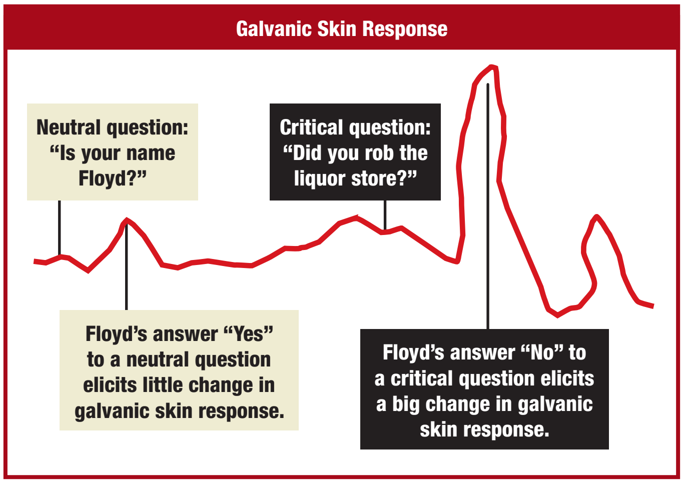
Neutral Questions

These are general questions, such as "Is your name Floyd?" or "Do you live at (a specific address)?" These questions are designed to elicit few, if any, emotional responses and are used to establish a baseline for normal physiological responding.

Critical Questions

These are specific questions about some particular crime or misconduct that only a person who committed the crime would know, such as "Did you rob the liquor store on 5th and Vine?" Critical questions are designed to elicit emotional responses, such as guilt or fear, if the person tells a lie.

As shown in the figure below, Floyd showed very little physiological arousal—as measured by the galvanic skin response—when asked a neutral question, "Is your name Floyd?" However, he showed great physiological arousal when asked a critical question, "Did you rob the liquor store?"



The examiner decides whether the client is lying or telling the truth by looking at the differences in physiological responses between neutral and critical questions. In Floyd's case, he answered "No" to a number of critical questions, such as "Did you rob the liquor store?" But his "No" answers were accompanied by large increases in galvanic skin response (as well as other responses). For those reasons, the examiner decided that Floyd had lied and thus failed the polygraph test. However, when the real robbers were eventually caught, tried, and sentenced, it proved that Floyd had not lied even though he failed the lie detector test twice. Floyd's case, as well as the Ames case, questions the accuracy of lie detector tests.

Photo Credit: © Visuals Unlimited/Corbis

How Accurate Are Lie Detector Tests?

Why aren't tests allowed in most courts?

If Floyd was innocent, why did he fail two lie detector exams? If Ames was lying, why did he pass two lie detector tests?

The basic problem with lie detector tests is that researchers have been unable to identify a pattern of physiological responses specific to lying. This means a number of different emotions—such as guilt, fear, or worry—can trigger physiological responses that make a person appear to be lying when he or she is telling the truth (Fiedler et al., 2002). Also, the polygrapher (person administering the polygraph test) can have a bias about the subject and not provide objective interpretations of the results (Haseltine, 2008). Because of these serious problems, researchers estimate that lie detector tests are wrong 25–75% of the time (Broad, 2002; Saxe, 1994).

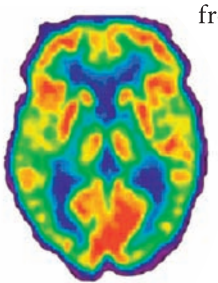
Although low error scores (5–10%) for some lie detector tests have been reported, these data come from less realistic laboratory settings that use simple tasks, such as identifying an object about which a subject—often a college student—has been told to lie (Ben-Shakhar & Elaad, 2003). The higher error scores come from studies that simulate more realistic conditions (Bashore & Rapp, 1993; Honts, 1994).

Innocent or faking. Besides high error scores, lie detector tests have two other problems: In one study, about 40% of subjects were judged to be lying or maybe lying when they were telling the truth (Honts, 1994); and in another study, about 50% of guilty people who were told to both press their toes to the ground and bite their tongues during control questions passed lie detector tests (Honts et al., 1994).

Restrictions. Because of the above problems, federal law prohibits most employers from using polygraph tests to screen employees, and most state and federal courts prohibit the use of polygraph evidence (Frazier, 2003). In 1998, the U.S. Supreme Court ruled that polygraph evidence cannot be used in most courts. However, 62% of local law enforcement agencies use lie detectors to screen new employees, and 75% of police believe polygraph tests are 86–100% effective (K. Johnson, 1999).

New tests. Recent concerns about terrorists and security have increased the need for more reliable methods to detect lies. One of the newest tests involves using brain scans to detect changes in thinking and associated neural activity that occur when lying. No area of the brain specializes in lying; however, researchers are finding increased activation in regions involved in suppressing information and resolving conflicts when an individual lies (Gamer et al., 2007; Kozel et al., 2005). Also, researchers studying structural brain abnormalities find that, compared to nonliars, pathological liars have 22% more prefrontal white matter, which is linked to the ability to deceive others (Yang et al., 2005a). Although these data are preliminary, they suggest that brain scans combined with clever questioning strategies may prove to be a more accurate and reliable way to detect lying (Gamer, 2009).

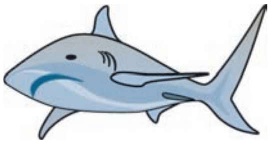
Other new tests aimed at improving the accuracy of lie detection include using eye scans to measure blood flow to the eye; observing very brief, involuntary facial expression changes; and analyzing the consistency and amount of detail in someone's testimony (Colwell, 2009; Ekman, 2006; Kluger & Masters, 2006).



Brain scan tests may be better than polygraph at detecting lies.

Summary Test

A. Peripheral Theories

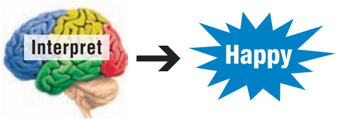


1. We can define an emotion in terms of four components: We interpret or appraise a (a) ________ in terms of our well-being; we have a subjective (b) ________; we experience various (c) ________ responses, such as changes in heart rate and respiration; and we often show (d) ________ behaviors, such as crying or smiling.

2. Several theories explain what causes emotions. Theories that emphasize changes in the body are called (a) ________ theories. One such theory states that emotions result from specific physiological changes in your body and that each emotion has a different physiological basis; this is called the (b) ________ theory. The major criticism of this theory is that different emotions do not always cause different patterns of physiological arousal. However, feedback from physiological changes may increase the (c) ________ of emotional feelings.

3. According to another peripheral theory, sensations or feedback from the movement of facial muscles and skin are interpreted by your brain and result in an emotion; this is called the (a) ________ theory. However, people with paralyzed facial muscles still experience emotions. Facial feedback may influence your (b) ________ as well as increase the (c) ________ of emotional feelings.

B. Cognitive Appraisal Theory

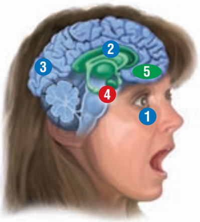


4. A theory of emotions that grew out of the work of Schachter and Singer says that your interpretation, appraisal, thought, or memory of a situation, object, or event can contribute to, or result in, your experiencing different emotional states. This is called the ________ theory.

C. Affective Neuroscience Approach

5. The most recent approach to understanding emotions studies the neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to our experiencing and expressing different emotional states. This is called the ________ approach.

6. Emotions have four qualities: They are expressed in stereotypical (a) ________ expressions and have distinctive (b) ________ responses; they are less controllable and may not respond to (c) ________; they influence many (d) ________ functions; and some emotions, such as smiling, are (e) ________ in the brain. The brain area that functions to detect and evaluate stimuli, especially threatening ones, and to store memories with emotional content is called the (f) ________. Because this brain structure receives sensory information so quickly, it triggers a fearful reaction without (g) ________. The brain structure involved in producing emotions from thoughts alone and in analyzing the emotional consequences of actions is called the (h) ________.

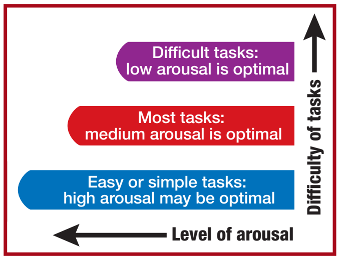


D. Universal Facial Expressions

7. Specific inherited facial patterns or expressions that signal specific feelings or emotional states across cultures, such as a smile signaling a happy state, are called (a) ________. These emotional expressions, which are said to include happiness, surprise, fear, anger, contempt, disgust, and sadness, are thought to have evolved because they had important (b) ________ functions for our ancestors. Evidence for universal emotions includes that people in different cultures recognize the same (c) ________ expressions, that infants in different cultures show a predictable (d) ________ in developing facial expressions, and that even blind children, who cannot observe their parents' faces, develop smiling at the same time as sighted children.

E. Functions of Emotions

8. Facial expressions that accompany emotions send signals about how one (a) ________ and what one intends to do. Emotions focus one's (b) ________ so one can better respond to emotional situations and also increases the (c) ________ of situations that may be either beneficial or dangerous to one's well-being.



Difficult tasks: low arousal is optimal
Most tasks: medium arousal is optimal
Easy or simple tasks: high arousal may be optimal
Difficulty of tasks
Level of arousal

9. According to one theory of emotions, we have inherited the neural structure and physiology to express and experience emotions and we evolved basic emotional patterns to adapt to and solve problems important for our survival; this is called the ________ theory.

10. There is a relationship between emotional arousal and your performance on a task; this relationship is called the (a) ________ law. According to this law, low arousal results in better performance on (b) ________ tasks; for most tasks, (c) ________ arousal helps performance; and for easy tasks, (d) ________ arousal may facilitate performance.

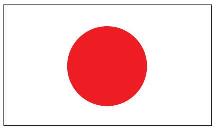
Photo Credits: top, © Digital Stock Corporation; bottom, © Photo24/Brand X Pictures/Getty Images

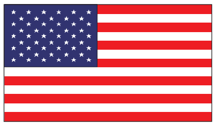
F. Happiness

11. Momentary pleasures, short-term joys, or long-term satisfaction can result in an emotional feeling called (a) ________________. This emotion also stimulates the brain's reward/pleasure center, which includes several areas, such as the (b) ________________ and ________________. Researchers estimate that one's personal level of happiness is set half by (c) ________________ influences and half by (d) ________________ factors.

12. One theory explains that we quickly become accustomed to receiving some good fortune (money, job, car, degree) and, within a relatively short period of time, take the good fortune for granted. As a result, this good fortune contributes little to our long-term level of happiness; this is called the (a) ________________ theory. Research shows that long-term happiness is less dependent upon (b) ________________ because we soon adapt to our good fortunes. Instead, long-term happiness is more dependent upon pursuing our own personal (c) ________________ and developing meaningful (d) ________________. One reason some people are generally more happy and some are generally less happy is that each of us seems to have a happiness (e) ________________, which is about half set or influenced by environmental factors and about half set or influenced by inherited or genetic factors.

G. Cultural Diversity: Emotions across Cultures





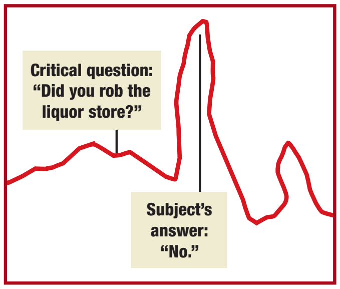
13. Although many emotional expressions are shared and recognized across cultures, it is also true that cultures have unique rules that regulate how, when, and where we should express emotion and how much emotion is appropriate; these rules are called ________________. For example, among the Inuit (Eskimos), feelings of anger are strongly condemned, but among certain Arab groups, a man's failure to respond with anger is seen as dishonorable.

14. Another example of display rules is from a study in which Americans and Japanese rated the intensity of five emotions—surprise, anger, happiness, disgust, and sadness—on a scale from 1 to 10. The emotion rated most intense by the Japanese was (a) ________________, while the Americans rated (b) ________________ as the most intense of the five emotions. This study illustrates how cultural display rules may differently influence how people perceive the (c) ________________ of emotions.

H. Research Focus: Emotional Intelligence

15. The ability to perceive and express emotion, understand and reason with emotion, and regulate emotion in oneself and others is called (a) ________________. One reason researchers believe that emotional intelligence is important is that the better we understand how emotions operate, the better are our chances of finding a way to work out compromises between our strong (b) ________________ feelings and our equally strong rational (c) ________________. We are able to share emotions felt by others because of our (d) ________________, which track the emotions of the person we are with and replicate the same emotions in us by activating our brains in the same way the other person's brain is activated.

I. Application: Lie Detection



16. The instrument that is sometimes referred to as a lie detector is correctly called a (a) ________________; it measures a person's heart rate, blood pressure, respiration, and emotionally induced hand sweating, which is called the (b) ________________ response. To determine whether a person is telling the truth or a lie, the examiner compares the person's physiological responses to (c) ________________ and ________________ questions. The basic problem with lie detector tests is that no pattern of physiological responses has been specifically associated with lying. This means that many emotions can cause increased physiological responses that make the person appear to be lying. Because of the relatively high (d) ________________ rate, evidence from lie detector tests is not admitted in most courts of law. The newest method to detect lies involves using brain scans to detect changes in thinking and associated (e) ________________ that occur when subjects lie.

Answers: *1. (a) stimulus, (b) feeling, (c) physiological, (d) overt; 2. (a) peripheral, (b) James-Lange, (c) intensity; 3. (a) facial feedback, (b) mood, overall feeling, (c) intensity; 4. cognitive appraisal; 5. affective neuroscience; 6. (a) facial, (b) physiological, (c) reason, (d) cognitive, (e) hard-wired, (f) amygdala, (g) awareness or conscious thought, (h) prefrontal cortex; 7. (a) universal emotions, (b) adaptive, survival, (c) facial, (d) order; 8. (a) feels, (b) attention, (c) memory, recall; 9. evolutionary; 10. (a) Yerkes-Dodson, (b) difficult, (c) medium, (d) high; 11. (a) happiness, (b) nucleus accumbens, ventral tegmental area, (c) genetic or inherited, (d) environmental; 12. (a) adaptation level, (b) wealth or material things, (c) goals, (d) relationships or friends, (e) set point; 13. display rules; 14. (a) disgust, (b) happiness, (c) intensity; 15. (a) emotional intelligence, (b) emotional, (c) thoughts, (d) mirror neurons; 16. (a) polygraph, (b) galvanic skin, (c) neutral, critical, (d) error, (e) neural activity*

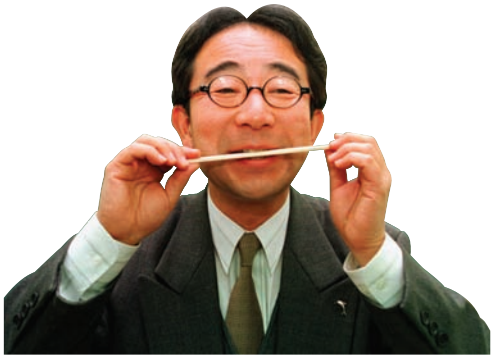
Critical Thinking

Why Do They Have to Learn to Smile?



In the United States it's very common to see people smiling in public because it's a friendly way to interact socially. In fact, many businesses insist that their salespeople smile at customers because smiling makes the customers feel more comfortable and more likely to buy something. But in Japan, people are very reluctant to show emotions in public and that's become a problem.

Japan is currently going through a recession or downturn in business, so there is increased competition to get new customers and keep current customers happy. Said one gas station attendant who is trying to learn to smile more, "In this recession, customers are getting choosy about their gas stations, so you have to think positively. Laughter and a smile are representative of this positive thinking" (Reitman, 1999, p. A1).

But getting salespeople to smile is a radical change in Japan, whose cultural tradition has long emphasized suppressing any public display of emotions, be it happy, sad, or angry. For example, women never smile at their husbands and members of families rarely touch in public and never hug, even when greeting after a long separation. It's still common for women to place a hand over their mouths when they laugh, and men believe that the correct and proper behavior is to show no emotions in public. Unlike American salespeople who often smile and make eye contact with their customers, Japanese salespeople are reserved and greet customers with a simple "welcome"; smiling, up until now, was totally frowned upon.

Because getting salespeople to smile is going against a strong tradition, learning how to smile has grown into a big business in Japan. Employees are now being sent to "smile school," which uses various techniques to teach reluctant and bashful students to smile. For example, one technique in learning how to smile is biting on a chopstick (photo above) and then lifting the edges of the mouth higher than the chopstick. Another technique is to follow "smile" instructions: "Relax the muscle under your nose, loosen up your tongue. Put your hands on your stomach and laugh out loud, feeling the 'poisons' escape" (Reitman, 1999, p. A1).

What is driving all this smiling in Japan is sales and morale. As is well known by American businesses, happy, friendly salespeople are usually the most successful and are great at building company morale. The same is holding true in Japan, where smiley clerks are racking up the most sales and creating a friendly morale.

People in other parts of Asia, such as China, also are not accustomed to smiling in social situations. In fact, volunteers for the 2008 Olympics in Beijing were required to take classes on how to smile to ensure that they portray China as hospitable. (Adapted from Mauss, 2005; Reitman, 1999; UPI, 2006)

QUESTIONS

1 In the United States, why is smiling in social situations considered an acceptable and even desirable way to behave in public?

2 When having to make money is bucking cultural traditions, what do you think will happen?

3 Even though emotional expressions, such as smiling, are considered universal facial expressions, why don't the Japanese smile more?

4 Why is it so difficult for many highly motivated Japanese to learn to smile?

5 Why do you think that smiley, friendly salespeople are more successful and better at building morale?

6 According to the facial feedback theory, how would not smiling influence emotions?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Smiling is one of the universal facial expressions, which means it occurs and is recognized as a friendly social signal worldwide. However, different countries have different display rules, which regulate how, when, and where its citizens can express emotions. The display rules for the United States encourage the public display of emotional expressions, such as smiling.
2. Cultural display rules have a strong influence on people's behavior (in the United States, women can cry but men should not). It takes a strong motivating force, such as money, to change the cultural display rules, such as making it OK to smile in Japan.
3. Unlike the United States, whose cultural display rules encourage public display of smiling, Japan has had a long tradition of cultural display rules that ban most public display of emotions.
4. Even though many businesses in Japan are now sending their employees to "smile school," employees are finding it difficult to learn to smile because they must first overcome a lifetime habit of not showing emotions. Imagine how men in the United States would feel if they were now encouraged to cry in public and were sent to "cry school" to learn how!
5. One reason smiley salespersons are usually more successful is that all their customers come with a built-in or inherited detector for facial expressions, such as smiling. When seeing a salesperson smile (universal facial expression), customers immediately detect that it's a friendly social signal and that the salesperson is acting friendly. As a result, customers feel more friendly and more motivated to agree with the salesperson's suggestions and buy.
6. The facial feedback theory states that the movements of your facial muscles and skin are interpreted by your brain as different emotions. If you aren't smiling, your brain doesn't receive feedback from those facial muscles, and as a result you don't experience the joy or happiness associated with smiling.

Nature-Nurture Question

Will Alex ever learn to love a parent?

For the first 3 years of his life, Alex was raised in an orphanage in Romania where the number of infants and children greatly exceeded the number of caregivers. At the orphanage, Alex was given adequate nutrition allowing him to develop well physically, but the affection, stimulation, and comfort he received were far from adequate. Alex, like other children living in Romanian orphanages, spent most of his days alone in a crib with almost no interaction with others. When he cried, no one came to hold or soothe him. He was never given the opportunity to bond with a caregiver.

When Alex was 3 years old, a family living in the United States adopted him. His adoptive mother described him as being friendly and engaging, but also "self-abusive" and having a "dark side." For instance, Alex would make himself go into a seizure by slamming his head on the floor. He was also aggressive toward others, one time attacking his younger sister, "beating her senseless." When asked if he wanted his adoptive mother to love him, he said to her, "I never want you to love me." When his adoptive mother asked him if he loved her, he replied, "No, I don't love anybody." After years of exhausting every treatment option and still unable to feel loved by Alex, his adoptive parents arranged for Alex to live with another family (Jarriel & Sawyer, 1997).

Until age 3, Alex lived in an orphanage where he didn't receive affection, stimulation, or comfort.

Children like Alex, whose emotional needs (such as forming a stable attachment with a caregiver) go unmet during infancy and early childhood, may develop reactive attachment disorder.

Reactive attachment disorder is a psychiatric illness characterized by serious problems in emotional attachments to others beginning before age 5. Some symptoms children may show include resisting comfort and affection by parents, being superficially engaging and overly friendly with strangers, having poor peer relationships, and engaging in destructive behavior to themselves and to others (American Psychiatric Association, 2000; G. C. Keck & Kupecky, 1995).

Do all children raised in Romanian orphanages who are later adopted have attachment problems? This question brings up an interesting issue in developmental psychology referred to as the nature-nurture question.

The ***nature-nurture question*** asks how much nature (genetic factors) and how much nurture (environmental factors) contributes to a person's biological, emotional, cognitive, personal, and social development.

Although the nature-nurture question seems like an abstract intellectual issue, it has very practical consequences. For example, in the United States, courts have varied in how they side with biological parents (nature) over adoptive parents (nurture) when awarding custody of an adopted child. Traditionally, courts have favored placement with biological parents, but more recently some courts have begun to favor placement with adoptive parents (M. Dolan, 2002). For example, Dana Wakefield, a juvenile court judge, adamantly states, "In my courtroom, they (children) stay where they've been nurtured. You have to consider who the child feels is the psychological parents. If they have a good bond in that home, I'm not about to break it" (Gibbs, 1993, p. 49).

There are now about 10,000 Romanian children growing up in the United States, and nearly all of them initially had serious developmental problems. One researcher studying the adjustment of over 300 Romanian adoptees in the United States found that after the first year, 20% of children reached normal development, 60% showed only mild problems, and the remaining 20% had serious cognitive, behavioral, and emotional problems (Fischer, 1999). The reason some Romanian adoptees have long-term developmental problems while others make significant improvements is complex, involving both biological (nature) and environmental (nurture) factors.

Developmental Psychologists

The questions about why Romanian adoptees vary in how they are affected by being raised in an orphanage and how they later adjust to adoption illustrate the kinds of issues and questions studied by developmental psychologists.

Developmental psychologists study a person's biological, emotional, cognitive, personal, and social development across the life span, from infancy through late adulthood.

7-year-old Alex still has serious problems in his emotional attachment to others.

Later in this module, we'll explain how Alex was doing at age 7 and what it means when he is finally able to say "I love you" to a parent. From the work of developmental psychologists, we have learned that the answer to the age-old question of whether nature or nurture is more important is that they are both important and their interaction is the key to understanding how an infant develops into a very complex adult with his or her own personality, behaviors, and goals (Pinker, 2003).

What's Coming

We'll discuss how development is affected by various prenatal factors, such as alcohol, which is the leading known cause of mental retardation. We'll explain the amazing abilities of newborns, the early appearance of a basic emotional makeup, the surprising growth of mental abilities, the different factors that influence social development, and the terrible occurrence of child abuse, which affects more than a million children a year.

We'll begin with a family whose infant son's unusual musical abilities showed how nature and nurture interact.

A. Prenatal Influences

Nature and Nurture

Was he born a violin player?

The reviewer for the *San Francisco Examiner* had listened to an inspired performance and wrote that the violinist "would one day be a master among masters" (Magidoff, 1973, p. 35).

At that point, the "master" was all of 5 years old and had been taking lessons for only six months. His name was Yehudi Menuhin. When Yehudi was 8 years old, he made his first professional appearance. The reviewer wrote, "This is not talent; it is genius!" (Magidoff, 1973, p. 46). Yehudi made his debut in New York at the age of 10, and the reviewer wrote, "What built the world in six days is what contrived the genius of Yehudi. He walks on the waves" (Magidoff, 1973, p. 52).

When only 8 years old, Yehudi made his professional debut.

The amazing musical abilities of young Yehudi certainly classify him as a prodigy.

A ***prodigy*** is a child who shows a highly unusual talent, ability, or genius at a very early age and does not have mental retardation. A small percentage of autistic children, who have some degree of mental retardation, may also show unusual artistic or mathematical abilities; they are called savants.

Because prodigies demonstrate such unusual abilities so early, they are excellent examples of the interaction between nature (genetic influences) and nurture (learned influences).

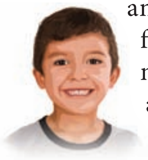
Genetic and Environmental Factors

One reason Yehudi Menuhin was a prodigy and could give an inspiring violin performance at the age of 5 was the prenatal (before birth) effects of genetic influences. Prenatal influences, in the form of genetic instructions, regulated the development of Yehudi's brain and body.

Parents. The father contributed half of Yehudi's genetic instructions (23 chromosomes), and the mother contributed half of the genetic instructions (23 chromosomes).

The father and mother were teachers, and both had musical interests. The father had taken six violin lessons when he was a boy, but his grandfather had forbidden him to play any further. The mother had musical ability and took regular cello lessons. Through their chromosomes, the parents passed some of their musical talents on to their three children, Yehudi and his two younger sisters.

Daughters. The two daughters each received half of their genetic instructions from their mother and half from their father. Both daughters, who were younger than Yehudi, showed early musical abilities and began playing piano at the ages of 5 and 7. It is difficult to tell if the daughters had as much natural ability as Yehudi because in the 1930s and 1940s there were few opportunities for women in professional music. As a result, these negative environmental influences actively discouraged the two daughters from developing their potential musical abilities.



Son. Yehudi received half of his genetic instructions from his mother and half from his father. The unique pairing of chromosomes from the mother and father results in different physical and mental traits for each of the three children. Because Yehudi and his two younger sisters showed great musical ability by age 5, we can assume that their early musical ability was primarily due to genetic or inherited instructions that came from their parents' chromosomes. However, certain environmental factors, such as few opportunities for women musicians, discouraged the sisters from developing their talents. Different environmental factors, such as more opportunities for male musicians, encouraged Yehudi to develop his musical talents.

Interaction. Yehudi Menuhin, who was universally hailed as the greatest child prodigy since Mozart, developed into a legendary violin performer (Magidoff, 1973). The development of Yehudi's musical talents is a perfect example of how nature and nurture interact. You can see that genetic influences (nature) played a major role in wiring his brain so that his incredible musical abilities appeared at a very early age, before he had a chance to learn them. You can also see that environmental influences (nurture), such as being taken to concerts from age 2 on and being encouraged to practice and take lessons, encouraged Yehudi to develop the musical talents that he had inherited from his parents.

Psychologists have long recognized the importance of learning influences, but it is only in about the past ten years that psychologists have also recognized the importance of genetic factors that influence almost every aspect of behavior, including cognitive, social, emotional, and personality development (C. Baker, 2004). Today, researchers no longer focus on which is more important, nature or nurture, but rather on how nature and nurture interact to influence and regulate our behaviors (Pinker, 2003).

Genetic instructions from our parents can result in our having a wide range of abilities. Next, we'll explain what happens when genetic instructions are damaged—for example, if the mother uses drugs during the prenatal period.

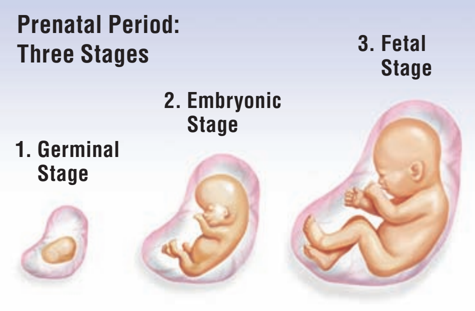
Prenatal Period: Three Stages

How did you begin?

You began as a single cell about the size of a grain of sand. In this tiny cell was the equivalent of about 300,000 pages of instructions for the development of your brain and body. This single cell marks the beginning of the prenatal period.

The ***prenatal period*** extends from conception to birth and lasts about 266 days (around nine months). It consists of three successive phases: the germinal, embryonic, and fetal stages. During the prenatal period, a single cell will divide and grow to form 200 billion cells.

As we examine the prenatal period, we'll unravel one of the great puzzles of science—how a human being begins, develops, and is born. We'll start with the germinal stage.



1 Germinal Stage

The germinal stage marks the beginning of our development into a human being.

The ***germinal stage*** is the first stage of prenatal development and refers to the two-week period following conception.

To understand how conception occurs, we need to back up a little and explain ovulation.

Only one of millions of sperm will fertilize this egg.

Ovulation is the release of an ovum or egg cell from a woman's ovaries.

In most cases, only a single ovum is released during ovulation, but sometimes two ova are released. If two separate ova are released and fertilized, the result is fraternal twins, who can be two brothers, two sisters, or a brother and sister. Because fraternal twins come from two separate eggs, they are no more genetically alike than any other two children of the same parents. In contrast, if a single ovum splits into two parts after fertilization, the result is identical twins, whose genes are almost indistinguishable.

How does conception take place?

If no sperm are present, there can be no fertilization, and the ovum, together with the lining of the uterus, is sloughed off in the process called *menstruation.* If, however, sperm have been deposited in the vagina (100–500 million sperm may be deposited with each act of intercourse), they make their way to the uterus and into the fallopian tubes in search of an ovum to be fertilized.

Conception, or ***fertilization,*** occurs if one of the millions of sperm penetrates the ovum's outer membrane. After the ovum has been penetrated by a single sperm (above photo), its outer membrane changes and becomes impenetrable to the millions of remaining sperm.

Once the ovum has been fertilized, it is called a ***zygote,*** which is a single cell that is smaller than the dot in the letter *i.* The zygote begins a process of repeated division and, after about a week, consists of about 150 cells. After two weeks, it has become a mass of cells and attaches itself to the wall of the uterus. Once the zygote is implanted, or attached to the wall of the uterus, the embryonic stage begins.

2 Embryonic Stage

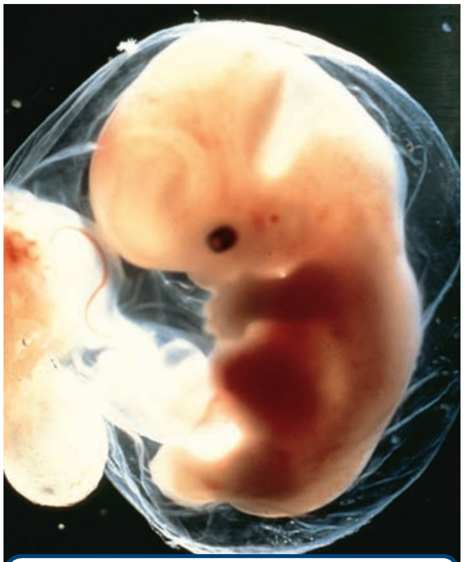
During this next stage, the organism begins to develop body organs.

The ***embryonic stage*** is the second stage of the prenatal period and spans the 2–8 weeks that follow conception; during this stage, cells divide and begin to differentiate into bone, muscle, and body organs.

At about 21 days after conception, the beginnings of the spinal cord and eyes appear; at about 24 days, cells differentiate to form what will become part of the heart; at about 28 days, tiny buds appear that will develop into arms and legs; and at about 42 days, features of the face take shape.

During this stage, the embryo is very fragile, since all of its basic organs are being formed. This is the time when most miscarriages occur and when most major birth defects occur (J. M. Nash, 2002).

Toward the end of the embryonic stage, the organism has developed a number of body organs, such as the heart. The embryo is only about 4 cm long but already has the beginnings of major body organs and limbs and begins to look somewhat human (Cunningham et al., 2009).



Embryo—about 6 weeks

In the left photo, you can see the head as the large rounded structure at the top, and the black dot on the side of the head is the developing eye. After this second stage of development, which is called the embryonic stage and lasts 2–8 weeks, comes the last stage, which is called the fetal stage.

A. Prenatal Influences

3 Fetal Stage

What is the fetal stage?

The embryonic stage is followed by the fetal stage.

The ***fetal stage,*** which is the third stage in prenatal development, begins two months after conception and lasts until birth.

Fetus in womb at 6 months

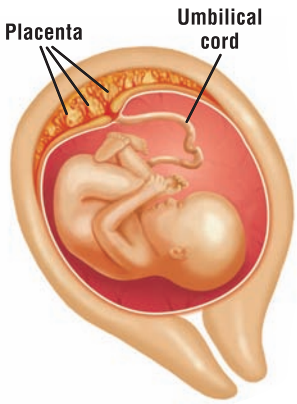
At the end of the fetal stage, usually 38–42 weeks after conception (or roughly nine months), birth occurs and the fetus becomes a newborn.

During the fetal stage, the fetus develops vital organs, such as lungs, and physical characteristics that are distinctively human. For example, at about six months a fetus has eyes and eyelids that are completely formed (right photo), a fine coating of hair, relatively well-developed external sex organs, and lungs that are beginning to function.

Infants born very prematurely (under six months) will have difficulty surviving because their lungs are not completely formed and they have difficulty breathing. However, a six-month-old fetus usually has lungs well enough developed to begin to show irregular breathing and, for this reason, can survive if born prematurely.

During stage 2, the embryonic stage, and stage 3, the fetal stage, the developing organism is especially vulnerable to toxic agents and chemicals. To help keep out these potentially harmful agents, the developing organism is protected by the placenta.

Placenta and teratogens. Because the fetus experiences rapid body growth and development of the nervous system, it is highly vulnerable to the effects of drugs and other harmful agents. However, the blood supply of the fetus is partly protected by the placenta (left figure) (Koren, 2007).



The ***placenta*** is an organ that connects the blood supply of the mother to that of the fetus. The placenta acts like a filter, allowing oxygen and nutrients to pass through while keeping out some toxic or harmful substances.

However, certain viruses, such as HIV, and many drugs, including nicotine, caffeine, marijuana, cocaine, and heroin, pass from the placenta into the fetus's blood vessels and thus can affect fetal development. These potentially dangerous agents are called teratogens.

A ***teratogen*** *(teh-RAT-oh-gen)* is any agent that can harm a developing fetus (causing deformities or brain damage). It might be a disease (such as genital herpes), a drug (such as alcohol), or another environmental agent (such as chemicals).

Besides harmful chemicals, drugs, and viruses, the developing fetus can also be affected by genetic problems, especially if the parents are carriers of potentially harmful genes (Tay-Sachs) or if the mother is in her forties, which increases the risk for certain fetal genetic problems (Down syndrome). In cases where fetal genetic problems are possible, the mother may wish to have her fetus tested by a relatively safe process called amniocentesis (M. B. Marcus, 2000).

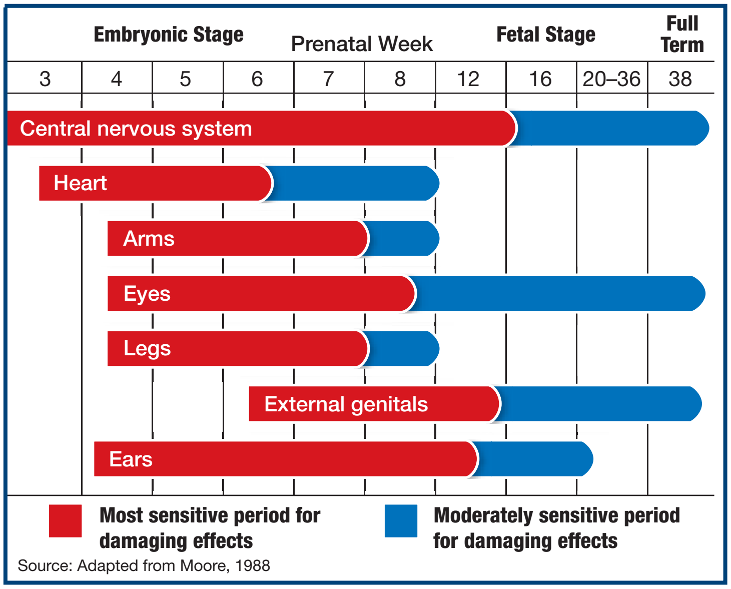
Birth defects and amniocentesis. During the fetal stage, a number of genetic errors can be tested for by amniocentesis *(AM-nee-oh-sen-TEE-sis).*

Amniocentesis, which is a medical test done between weeks 14 and 20 of pregnancy, involves inserting a long needle through the mother's abdominal muscles into the amniotic fluid surrounding the fetus. By withdrawing and analyzing fetal cells in the fluid, doctors can identify a number of genetic problems.

One genetic problem identified by amniocentesis is Down syndrome (p. 288). The risk for it increases in mothers who are in their forties (Cunningham et al., 2009).

Down syndrome results from an extra 21st chromosome and causes abnormal physical traits (a fold of skin at the corner of each eye, a wide tongue, heart defects) and abnormal brain development, resulting in degrees of mental retardation.

Besides Down syndrome, more than 1,000 other genetic disorders can now be tested for and identified (Weil, 2006). A combination of various relatively noninvasive screening tests completed during the first and second trimesters can detect Down syndrome up to 96% of the time. More invasive fetal DNA testing is even more definitive (Kotz, 2007b; Malone et al., 2005). As shown in the graph below, birth defects can occur if something (toxin, drug, genetic malfunction) interferes with developing structures, especially during the embryonic stage (J. M. Nash, 2002).



Source: Adapted from Moore, 1988

Next, we'll discuss several teratogens (from the Greek word *tera,* meaning "monster") that can pass through the placenta and interfere with fetal growth and development.

Drugs and Prenatal Development

How well is the fetus protected?

In the womb, the fetus is protected from physical bumps by a wraparound cushion of warm fluid. The fetus is also protected from various teratogens (certain chemicals and drugs) by the filtering system of the placenta (described on p. 380). However, we'll discuss several drugs, both legal and illegal, that can pass through the placenta, reach the fetus, and cause potential neurological, physiological, and psychological problems.

Drug Use and Exposure to Chemicals

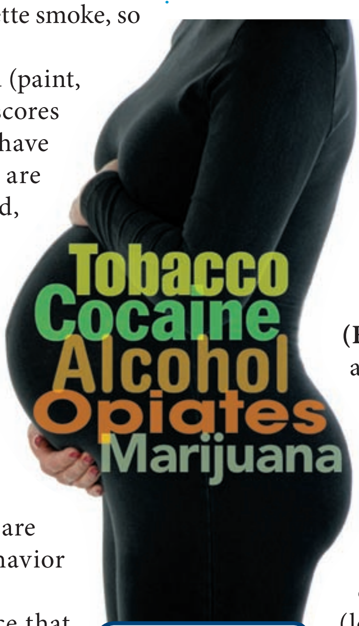
Caffeine. Pregnant women who use caffeine, even as little as one cup of coffee a day, are at higher risk of having an underweight baby. Babies born underweight are more likely to have health problems as adults, such as high blood pressure and diabetes (CARE, 2008).

Cocaine plus other drugs. Pregnant women who use crack cocaine along with other drugs, such as alcohol, tobacco, or marijuana, have infants with low birth weights, poor feeding habits, and risks for developing other psychological problems, such as low IQ scores and poor coping skills (Bendersky & Lewis, 1999). Research shows it is not the cocaine alone that is responsible for these problems but rather the combination of drugs (D. A. Frank et al., 2001).

Smoking and nicotine. Smoking during pregnancy increases the risk of low birth weight, preterm deliveries, and possible physical problems (Cunningham et al., 2009). In addition, infants born to smoking mothers have an increased risk for developing attention-deficit/hyperactivity disorder (p. 27), sudden infant death syndrome (SIDS), oral clefts (birth defect of mouth and lips), and respiratory infections (J. Braun et al., 2006; Dambro, 2006; G. M. Shaw et al., 2009). Women who smoke during pregnancy should remember that when they inhale cigarette smoke, so does their fetus.

Lead. Children exposed to large amounts of lead (paint, gasoline, industry) during pregnancy have low IQ scores and problems in brain development. Researchers have also found that even lower levels of lead exposure are associated with low IQ scores in children (Canfield, 2003). Also, there appears to be a link between lead exposure in the womb and during childhood and attention and hyperactivity problems as well as criminal and antisocial behavior in adulthood, such as assaults, robbery, arson, and disorderly conduct (J. Braun et al., 2006; Dietrich, 2003; J. P. Wright et al., 2008). Last, childhood lead exposure is linked to a smaller brain region that is responsible for decision making and impulse control during adulthood, which may explain why these adults are more likely to exhibit criminal and antisocial behavior (Bellinger, 2008).

Air pollutants. New research provides evidence that prenatal exposure to air pollutants, such as gasoline, diesel, and coal, has a negative impact on children's cognitive development. Also, pregnant women exposed to high levels of air pollutants are more likely to have children with low birth weights, fetal growth deficiencies, and delays in physical development. Because it is not possible for pregnant women to completely avoid exposure to air pollutants, environmental changes in vehicles and power plants are important (Harder, 2006; Rich et al., 2009).

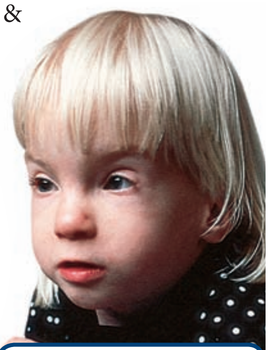


These drugs can affect the developing fetus.

Alcohol

Heavy drinking—Fetal alcohol syndrome (FAS). In the United States, alcohol is the leading known cause of mental retardation. Alcohol (ethanol) is a teratogen that crosses the placenta, affects the developing fetus, and can result in fetal alcohol syndrome (S. L. Fryer et al., 2007; Riley & McGee, 2005).

Fetal alcohol syndrome, or ***FAS,*** results from a mother drinking heavily during pregnancy, especially in the first 12 weeks. FAS results in physical changes, such as short stature, flattened nose, and short eye openings (right photo); neurological changes, such as fewer brain connections within the brain structure; and psychological and behavioral problems, such as hyperactivity, impulsive behavior, deficits in information processing and memory, alcohol and drug use, and poor socialization.



Facial features associated with FAS

Children with fetal alcohol syndrome continue to have problems into adolescence and adulthood. For example, follow-up studies up to 21 years after the original diagnosis indicated that FAS individuals tended to remain short, had an average IQ of 68 (normal is 100), were likely to be easily distracted and to misperceive social cues, and were at risk for developing drinking and drug problems (Baer et al., 2003; Streissguth et al., 1999). This means that various physical, neurological, psychological, and behavioral problems associated with fetal alcohol syndrome are long-lasting.

Moderate drinking—Fetal alcohol effects (FAE). Recently, researchers found that moderate drinking (7–14 drinks per week) by pregnant women does not usually result in fetal alcohol syndrome (FAS). However, moderate drinking may result in fetal alcohol exposure (FAE), which is less severe than fetal alcohol syndrome but more prevalent. Researchers report children with prenatal exposure to alcohol can have growth deficiencies and deficits in a number of cognitive tasks (learning and memory), academic skills, and fine motor speed and coordination (CDC, 2005; Wattendorf & Muenke, 2005). Researchers say there is no safe level of alcohol use during pregnancy, and therefore it is recommended that women who are pregnant or are planning a pregnancy should not drink any alcohol (Gorman, 2006).

We have discussed the three stages of prenatal development, which end with the baby's birth. After the baby gets a pat on the backside and lets out a cry, he or she is ready to take on the world.

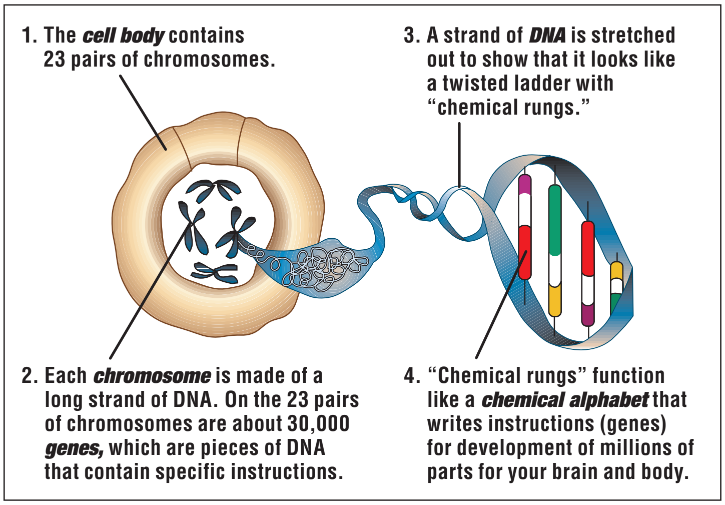
B. Newborns' Abilities

Why can't a newborn walk?

Some animals, such as baby elephants (150 pounds), can walk immediately after birth. In comparison, baby humans (7 pounds) cannot walk because neither their leg muscles nor brain areas are well enough developed. However, human infants are born with a surprising number of sensory and motor abilities, such as hearing, grasping, and sucking. How these abilities develop is explained by an inherited genetic program.

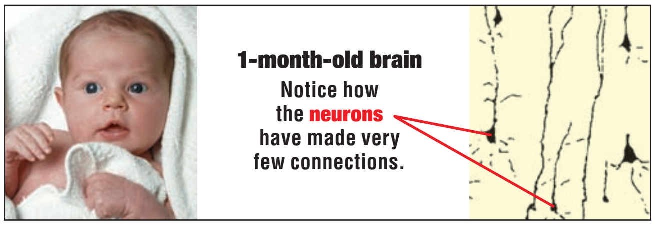
Genetic Developmental Program

Conception results in a fertilized egg, which has a genetic program that is equivalent to 300,000 pages of typed instructions for developing the body and brain. The mother and father each contribute 23 chromosomes so each child receives a unique genetic program.



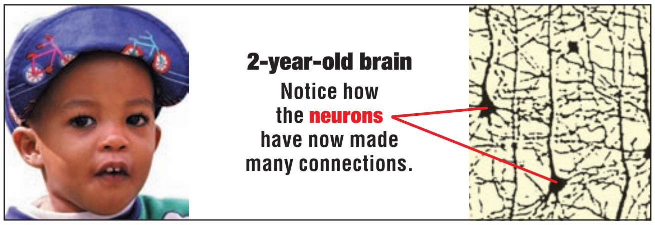
1. The ***cell body*** contains 23 pairs of chromosomes.
2. Each ***chromosome*** is made of a long strand of DNA. On the 23 pairs of chromosomes are about 30,000 ***genes,*** which are pieces of DNA that contain specific instructions.
3. A strand of ***DNA*** is stretched out to show that it looks like a twisted ladder with "chemical rungs."
4. "Chemical rungs" function like a ***chemical alphabet*** that writes instructions (genes) for development of millions of parts for your brain and body.

Brain growth. After birth, the genetic program regulates how the brain develops, such as making thousands of connections between neurons. For example, during the first three months of life, the most active areas of the newborn's brain are involved in processing sights, sounds, and touches, preparing the infant for dealing with sensory information from the surrounding environment.



1-month-old brain

Notice how the **neurons** have made very few connections.



2-year-old brain

Notice how the **neurons** have now made many connections.

In the figures above, notice that a 1-month-old brain has very few neural connections, while a 2-year-old brain has many thousands. This enormous increase in neural connections partly explains why the weight of a baby's brain increases from 25% to 75% of its adult weight between birth and 2 years old (Sigelman & Rider, 2006).

Sensory Development

During the nine months of development in the womb, a genetic program is guiding the development of a number of motor and sensory functions that are important for the newborn's survival. Here's a summary of a newborn's sensory abilities.

Faces. Newborns show a preference for their mother's face over strangers' faces in the first few days after birth. Apparently newborns first learn to recognize a person's eyes, a process that occurs through positive stimulation, such as caressing and suckling (E. M. Blass & Camp, 2001). Beginning at 4 months of age, an infant can ***visually*** distinguish his or her mother's face from a stranger's or an animal's (Wingert & Brant, 2005). By 3 or 4 years of age, an infant's visual abilities are equal to those of an adult.

Hearing. One-month-old infants have very keen hearing and can discriminate small sound variations, such as the difference between ***bah*** and ***pah***. By 6 months, infants have developed the ability to make all the sounds that are necessary to learn the language in which they are raised (Pascalis et al., 2002).

Touch. Newborns also have a well-developed sense of touch and will turn their head when lightly touched on the cheek. Touch will also elicit a number of reflexes, such as grasping and sucking.

Smell and taste. Researchers found that 1-day-old infants could discriminate between a citrus odor and a floral odor (Sullivan et al., 1991). Six-week-old infants can smell the difference between their mother and a stranger (Macfarlane, 1975). Newborns have an inborn preference for both sweet and salt and an inborn dislike of bitter-tasting things.

The senses develop relatively fast.

Depth perception. By the age of 6 months, infants have developed depth perception, which was tested by observing whether they would crawl off a visual "cliff" (E. J. Gibson & Walk, 1960).

A ***visual cliff*** is a glass tabletop with a checkerboard pattern over part of its surface; the remaining surface consists of clear glass with a checkerboard pattern several feet below, creating the illusion of a clifflike drop to the floor.

An infant is placed on the area with the checkerboard pattern and is encouraged to creep off the cliff. Six-month-old infants hesitate when they reach the clear glass "dropoff," indicating that they have developed depth perception.

Although the genetic program is largely responsible for the early appearance of these sensory abilities, ***environmental stimulation,*** such as parental touch and play, encourages the infant to further develop these sensory abilities (Collins et al., 2000).

Motor Development

Why do infants crawl before they walk?

"Gloria just took her first step." Parents are proud to note their child's motor accomplishments, which are primarily regulated by a built-in genetic program. As infants learn to crawl and walk, they change from passive observers into very active participants in the family's social life. The first area studied by early developmental psychologists was motor skill development (Thelen, 1995).

Motor development **refers to the stages of motor skills that all infants pass through as they acquire the muscular control necessary for making coordinated movements.**

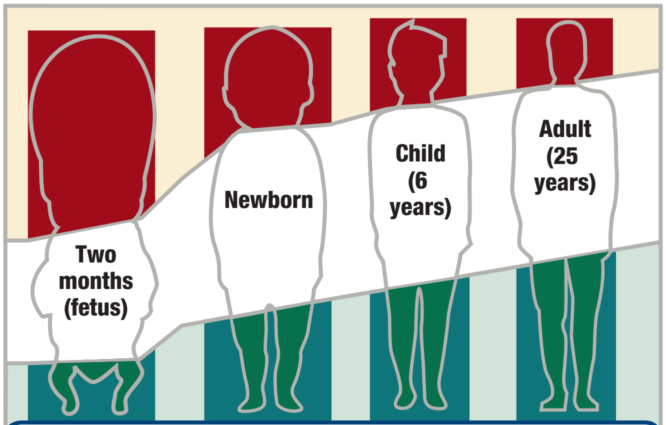
Because each child has a unique genetic program, he or she will acquire motor skills at different times (Hadders-Algra, 2002). The development of early motor skills, such as sitting, crawling, and walking, follows two general rules, called the proximodistal and cephalocaudal principles.

1 **The** ***proximodistal principle*** **states that parts closer to the center of the infant's body (*proximo* in Latin means "near") develop before parts farther away (*distal* in Latin means "far").**

For example, activities involving the trunk are mastered before activities involving the arms and legs. For that reason, infants can roll over before they can walk or bring their arms together to grasp a bottle.

2 **The** ***cephalocaudal principle*** **states that parts of the body closer to the head (*cephalo* in Greek means "head") develop before parts closer to the feet (*caudal* in Greek means "tail").**

For example, infants can lift their heads before they can control their trunks enough to sit up, and they can sit up before they can control their legs to crawl. In the figure below, notice the head area (larger) developing before the feet area (smaller).



Head size decreases in proportion to body size.

3 The cephalocaudal and proximodistal principles, which regulate the sequence for developing early motor skills, are part of a process known as maturation.

Maturation **refers to developmental changes that are genetically or biologically programmed rather than acquired through learning or life experiences.**

In developing motor skills (three right photos), such as sitting up alone, crawling, and walking, all infants in all parts of the world go through the same developmental stages at about the same times. However, if children are given more opportunities to practice their stepping reflex earlier in life, they will begin to walk at an earlier age than children who lack such opportunities (Thelen, 1995). Thus, the development of early motor development is heavily influenced by maturation (genetic program) but the timing can be partly slowed or speeded up by experience/learning (nurture).

Sitting up alone—average 5.5 months (range 4.5–8.0 months)

4 Parents often note the major milestones in their infants' motor development, such as their first time crawling or walking, because they want to know if their children are within the developmental norms.

Developmental norms **refer to the average ages at which children perform various kinds of skills or exhibit abilities or behaviors.**

Some examples of developmental norms for stages in walking accompany the three photos. Because norms for motor development represent average ages rather than absolute ages, parents should not be disturbed if their infant's motor progress does not match the norms.

Crawling—average 10 months (range 7.0–12.0 months)

By the age of 2, infants have grown into toddlers who can walk up and down stairs and use their hands to hold glasses of juice, operate toys, and, of course, get into a lot of trouble.

5 The reason infants develop skills and abilities at different times is that neural connections develop at different rates. This means that infants cannot perform complex cognitive, sensory, or motor tasks, such as walking, talking, and reading, until appropriate areas of their brains develop neural connections.

Walking alone—average 12.1 months (range 11.5–14.5 months)

Although we have focused on the role of the genetic developmental program (nature), it's important to remember that nature interacts with the environment (nurture) to encourage or discourage the development of various motor, sensory, and cognitive abilities (Hadders-Algra, 2002). For example, infants need appropriate ***environmental stimulation*** for development of their visual systems (see things), for learning to speak (hear parents speaking), for emotional development (get loving care), and for motor development (explore objects). These examples show how the genetic program needs and interacts with environmental stimulation for the proper development of a child's sensory, motor, and cognitive abilities.

Along with developing motor skills, an infant is also showing emotional changes.

C. Emotional Development

Definition

How can sextuplets be so different?

Becki is describing the emotional makeup of her sextuplets (photo below). "Brenna, the oldest by 30 seconds, is the affectionate one. Julian, the second child delivered, is 'Mr. Smiley.' Quinn, the third, is sweet and generous and most adventurous. Claire, fourth oldest, is the boss, as charming as she is tough. Ian, the fifth, is the smallest and loves music, drawing, and sleep. Adrian, the youngest, is the biggest and most gentle" (S. Reed & Breu, 1995, p. 127). Each of these 2-year-old sextuplets has a unique emotional development (J. Bates, 2004).

Each one has a different emotional makeup.

Emotional development refers to the influence and interaction of genetic factors, brain changes, cognitive factors, coping abilities, and cultural factors in the development of emotional behaviors, expressions, thoughts, and feelings (Goldsmith, 2003).

Similar to all infants, the sextuplets initially showed a limited number of inherited emotional expressions, including interest, startle, distress, disgust, and a neonatal smile (a half-smile that appears spontaneously for no apparent reason). Also, similar to all infants, during the first two years the sextuplets developed a wide range of emotional expressions and feelings, including ***social smiling*** (age 4–6 weeks); ***anger, surprise,*** and ***sadness*** (age 3–4 months); ***fear*** (age 5–7 months); ***shame*** and ***shyness*** (age 6–8 months); and ***contempt*** and ***guilt*** (age 24 months) (Kopp & Neufeld, 2003).

A child's increase in emotional expressions and feelings results from the interaction among genetic, neurological (brain), cognitive, coping, and cultural factors. The interaction of all these factors explains why each of the sextuplets has a unique emotional makeup, ranging from being sweet and gentle to being charming, adventurous, and tough.

We'll focus on one of the genetic factors involved in emotional development, which is called temperament.

Temperament and Emotions

Why did the differences show up so early?

One reason each of the sextuplets developed such a different emotional makeup so very early in life involves something called temperament.

Temperament refers to relatively stable and long-lasting individual differences in mood and emotional behavior, which emerge early in childhood because these differences are largely influenced by genetic factors.

Researchers studied differences in infants' temperaments by interviewing mothers with 2- to 3-month-old infants and then observing these same infants repeatedly over the next seven years. Researchers rated each infant on nine components of temperament, including activity level, attention span, fussiness, and mood. On the basis of these ratings, they divided infants into four categories (A. Thomas & Chess, 1977).

1 **Easy babies,** who made up 40% of the sample, were happy and cheerful, had regular sleeping and eating habits, and adapted quickly to new situations.

2 **Slow-to-warm-up babies,** who made up 15% of the sample, were more withdrawn, were moody, and tended to take longer to adapt to new situations.

3 **Difficult babies,** who made up 10% of the sample, were fussy, fearful of new situations, and more intense in their reactions. During the course of the seven-year study, difficult babies developed more serious emotional problems than the easy or slow-to-warm-up babies.

4 **No-single-category babies,** who made up 35% of the sample, had a variety of traits and could not be classified into one of the other three categories.

Genetic influence. Infants develop distinct temperaments very early, usually in the first 2–3 months of life, and these temperaments occur largely because of genetic factors rather than learning experiences (J. Bates, 2000). For example, about 10–15% of Caucasian babies inherit an inhibited or fearful temperament (e.g., show physiological arousal in novel situations), while about 40% inherit a fearless temperament (e.g., remain calm in novel situations) (Kagan, 2003a).

10% fearful

40% fearless

Differences in temperament are also observed in brain activity. For example, outgoing and friendly 9-month-old babies show increased activity in parts of the brain responsible for positive emotions (Wingert & Brant, 2005). Also, infants with highly reactive or fearful temperaments at 4 months of age are ten times more likely to develop depression and anxiety disorders during adulthood than less reactive or less fearful infants. The adults who are highly reactive as infants have overdeveloped brain areas responsible for emotional responses, which likely interferes with the proper functioning of these brain areas, leading to mood disorders (C. Schwartz, 2008, 2009).

Environmental influence. About 30% of infants who began with a fearful or fearless temperament remained that way emotionally into adulthood, but 70% showed moderate changes in temperament. One reason for changes in temperament involves environmental factors, such as family influence, poverty level, and educational opportunities, all of which interact with and can change the infant's initial temperament (Kagan 2003b). Thus, whether or not an infant's genetically influenced temperament persists into adolescence and adulthood depends to a considerable extent on the influence and interaction of environmental factors.

Because an infant's temperament influences the development of emotional behavior, it also affects the bond or attachment between parent and child, our next topic.

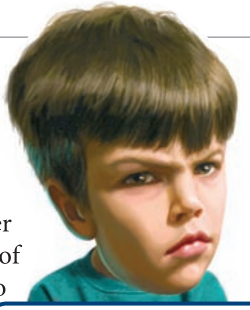
Attachment

Do infants and parents form a special bond?

For the first 3 years of his life, Alex (right picture) lived in an orphanage where he had no consistent, loving person to take care of him. When he was adopted at age 3, he repeatedly rejected his parents' love and he was never able to express love toward them. Living his first few years of life without close bonding to a parent or caregiver led Alex to have problems in attachment.

Attachment **is a close, fundamental emotional bond that develops between the infant and his or her parents or caregiver.**



Alex lived in a Romanian orphanage until he was adopted at age 3.

Psychologist John Bowlby (1969) believed that attachment behavior evolved through a process of natural selection. According to his theory, attachment evolved because of its adaptive value, which was to give the infant a better chance of surviving because the parent was close by to provide care and protection. Much of the research on attachment was initiated by Mary Ainsworth (1989), who asked three general questions: How does attachment occur? Are there different kinds of attachment? What are the long-term effects of attachment?

How Does Attachment Occur?

According to attachment theory, babies form an attachment to their parents through a gradual process that begins shortly after birth and continues through early childhood. As newborns, infants have a powerful social signal, crying, which elicits care and sympathy. As 4- to 6-week-old infants, they will begin social smiling (smiling at others), which will elicit joy and pleasure in their parents. At about 6 months, infants begin to give their parents a happy greeting (smiling, holding out their arms) when they reappear after a short absence. These behaviors contribute to children expressing their needs better and understanding their parents' emotional experiences, which ultimately help to build a good parent–child attachment (R. A. Thompson, 1998, 2006).

As the infant develops a closer attachment to her parents, she also shows more distress when her parents leave; this is called separation anxiety.

Separation anxiety **is an infant's distress—as indicated by loud protests, crying, and agitation—whenever the infant's parents temporarily leave.**

According to Ainsworth, separation anxiety is a clear sign the infant has become attached to one or both parents. By the end of the first year, an infant usually shows a close attachment to her parents as well as to one or more other family members.

However, depending on the infant's temperament (easy or difficult) and the mother's attitude (caring or not responsive), different kinds of attachment occur.

Are There Different Kinds of Attachment?

Ainsworth (1979) is best known for developing a method for studying infants' reactions to being separated from, and then reunited with, their mothers. She used these reactions to indicate the kind or quality of the infants' attachment. There are now four different kinds of attachment, but we'll focus on two, which are called secure (65% of infants) and insecure (20% of infants) attachment.

Secure attachment **is characteristic of infants who use their parent or caregiver as a safe home base from which they can wander off and explore their environments.**

For example, when infants are placed in an unfamiliar room containing many interesting toys, securely attached infants tend to explore freely as long as their parent looks on. If the parent leaves, most of the infants cry. On the parent's return, securely attached infants happily greet the caregiver and are easily soothed. In contrast, some infants show insecure attachment.

Insecure attachment **is characteristic of infants who avoid or show ambivalence or resistance toward their parent or caregiver.**

For example, insecurely attached infants may cling and want to be held one minute but squirm and push away the next minute, displaying a lack of trust in the parent or caregiver.

Researchers found that an infant's sense of trust or attachment was not affected by whether or how long a child was in day care. Instead, what most affected the infant's attachment was a mother's sensitivity, caring, and responsiveness to the infant's needs (NICHD, 1997). Attachments formed in infancy may also affect one's later relationships.

What Are Effects of Attachment?

Because Alex never formed an attachment to a parent during infancy, he will likely have difficulty forming healthy bonds with parents or other adults in the future. As it turned out, despite being adopted by parents who cared tremendously for him and tried every day to show they loved him, Alex never bonded with them. Even at age 7, he still rejected his parents' affection and did not trust them. Because Alex never developed a secure attachment, when the time came to say good-bye to his parents and meet his new adoptive mother, he left his parents without any hesitation and he immediately called the new woman "mom" and he also told her "I love you."

The kind of attachment formed in infancy is thought to be associated with the success of future relationships. For example, a secure attachment is associated with being more trusting, enjoying relationships more, and dealing better with stress; an insecure attachment is associated with being dependent and having poor social relationships and poor coping skills (Burge et al., 1997; M. S. Howard & Medway, 2004).

Our relationship with our parents is also important as we get older. In Module 18 (p. 413), we discuss how parenting styles influence the cognitive and emotional development of teenagers.

The kind of attachment an infant forms is partly dependent on temperament. We'll next discuss the kinds and effects of different temperaments.

D. Research Focus: Temperament

Are Some Infants Born Fearful?

How can children be so different?

We're going to discuss a series of classic studies by Jerome Kagan (2003a) that changed the way we think about children's temperaments. Kagan wanted to answer a question asked by many parents: Why do children raised by the same parents in the same family grow up with such different emotional makeups? For example, Eric's parents wondered why he (similar to circled child in right photo) was more shy and fearful than his two brothers, would never leave his mother's side to play with other children, was afraid to tell a story to his grade-school class, and feared going into the swimming pool with other children (Elias, 1989). Kagan wondered if Eric was born "fearful" and if he would change as he grew up.

Why is only one child shy?

The first problem Kagan faced was to select between two different research methods—longitudinal and cross-sectional methods—to study developmental changes. As we discuss the advantages and disadvantages of each method, you'll understand why Kagan selected the longitudinal method to study temperament.

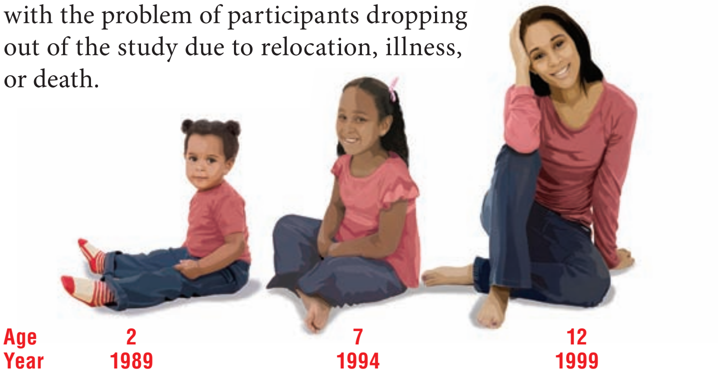
Longitudinal Method

One method researchers use to study developmental changes, such as a child's temperament, is the longitudinal method.

A ***longitudinal method*** means that the same group of individuals is studied repeatedly at many different points in time.

For example, as shown in the figure below, researchers first measure temperaments in a group of 2-year-old children, retest this same group again at age 7, then test them again at age 12, and so on.

Disadvantages. Disadvantages are that researchers must wait many years for their participants to grow older and they must deal with the problem of participants dropping out of the study due to relocation, illness, or death.



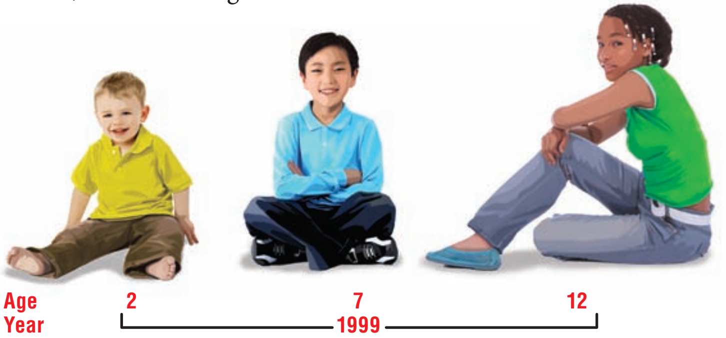
Advantage. A major advantage of the longitudinal method is that the same participants are used throughout the study. This means that researchers can track and analyze the development of each participant as he or she ages and confronts new environmental conditions. This ability to track each participant across time is the chief reason researchers prefer to use the longitudinal method to study developmental changes, such as changes in temperament.

Cross-Sectional Method

A ***cross-sectional method*** means that several groups of different-aged individuals are studied at the same time.

For example, in the figure below, researchers are using the cross-sectional method because they selected a group of 2-year-olds, a group of 7-year-olds, and a group of 12-year-olds and measured their temperaments at the same time.

Advantage. The primary advantage of the cross-sectional method is that researchers can compare any developmental differences, such as in temperaments, across many different age groups, all at the same time. This lowers the dropout rate due to relocation, illness, or death and gives immediate results.



Disadvantage. A major disadvantage of the cross-sectional approach is that it does not track the development of the same person across time but rather compares different groups at different ages. This means that both the participants and the environmental conditions are different, which allows for more error and bias in interpreting the results.

Procedure

Choosing the longitudinal method, Jerome Kagan and his colleagues (Kagan, 2003a; Kagan & Snidman, 1991) began by studying the temperaments of 4-month-olds. These same infants would be retested at different ages, until they reached their early 20s. The initial findings were that some 4-month-olds were fearless while others were fearful, whom he called inhibited children.

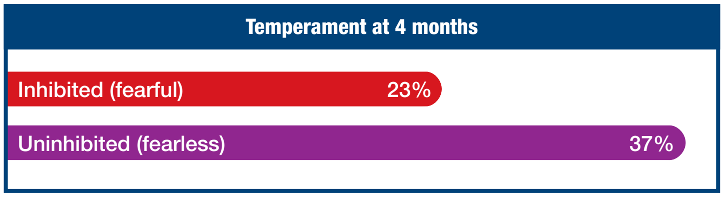
Inhibited/fearful children show avoidance, anxiety, or fear (measured by avoiding or crying) when in a strange or novel environment; they also show increased physiological arousal (increased heart rate) and brain activity (increased response of amygdala—threat detector) to novel or strange situations.

Having identified infants with two very different temperaments—inhibited/fearful and fearless—Kagan and his colleagues were able to study how these different temperaments affected emotional development by retesting the same participants across more than 20 years. Here's what they found.

Photo Credits: top, © LWA/Dann Tardif/Getty Images; bottom © Kayoco/zefa/Corbis

Results

How many were fearful/inhibited? Kagan and his colleagues observed several hundred 4-month-old infants and reported that about one-fourth were classified as inhibited or highly fearful (graph below). An inhibited or highly fearful ***infant*** showed a high degree of avoidance, fretting, and crying in novel or strange situations. A typical inhibited ***child*** stayed at the periphery of a large group of peers, reading a book, painting at an easel, or standing in a corner quietly watching another child. One of the best indicators of an inhibited child was that he or she spoke very little and initiated very little spontaneous conversation with unfamiliar peers or adults (Kagan et al., 1988; Kagan & Snidman, 1991).

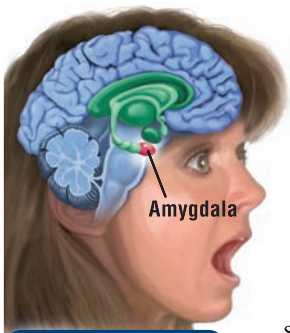


How many were fearless/uninhibited? About one-third of the ***infants*** were classified as uninhibited or low-fear individuals (above graph), and the remaining infants were classified in between. A typical fearless/uninhibited ***child*** was involved in group activities, was very talkative, initiated spontaneous interactions, engaged in conversations, often with smiling and laughter, and showed enthusiasm for social interactions not observed in inhibited children.

Based on these studies, as well as studies that compared identical twins (share nearly 100% of their genes) with fraternal twins (share 50% of their genes), researchers concluded that the influence of genetic factors on emotional development is as high as 60% (Goldsmith, 2003).

How many changed temperaments? About 18% of the very fearful infants remained highly fearful at 14 and 21 months and developed anxious symptoms at about 7 years, but about 80% of infants who were initially classified as very fearful did not develop into very fearful children. However, none of the very fearful children developed into completely fearless ones. This means that having a fearful temperament at infancy puts a person at risk for becoming a fearful child, but the risk for becoming fearful is not completely determined because some do become less fearful (but never fearless) (Kagan, 2003a).

What happens in the brain? Earlier we discussed the brain's emotional detector, called the amygdala (p. 362), which signals threatening or fearful stimuli. Researchers guessed that perhaps fearful infants were born with a more active amygdala. Researchers measured the amygdala's activity (fMRI) in response to novel or familiar faces in 20-year-old adults who had been classified as either fearful or fearless at age 2. Researchers found that adults classified as ***fearful*** at age 2 had more activity in response to novel faces than did adults initially classified as ***fearless.*** Researchers suggested that an infant who is born with an overactive amygdala is at risk for having a fearful temperament and later developing into a fearful or shy person (C. E. Schwartz et al., 2003).



Fearful adults had more activity in the amygdala.

How can parents help a fearful/inhibited child overcome his or her fear and shyness?

Conclusions

This research answers a question asked by many parents: How can children raised by the same parents in the same family have such different temperaments? Part of the answer comes from Kagan's (2003a) series of longitudinal studies, which showed that infants have at least two distinct temperaments—fearful/inhibited or fearless/uninhibited. These two temperaments are relatively stable across time and involve observable behaviors (avoiding and crying), physiological arousal (increased heart rate), and differences in the activity of the brain's emotional detector, the amygdala.

Being fearful is one kind of temperament.

The occurrence of different temperaments in young infants indicates the influence of genetic factors (nature). However, the finding that about 80% of the children's temperaments changed moderately indicates the influence of environmental experiences (nurture) (Pesonen et al., 2003).

Another interesting finding was that although children differed in temperament—inhibited or uninhibited—they did not differ in IQ scores, intellectual abilities, language, memory, or reasoning abilities (Kagan, 1998).

How can parents help fearful children? Researchers advise parents with fearful children to be very caring and supportive and to consistently help their inhibited children deal with minor stressors. With such support, inhibited children learned to control their initial urges to withdraw from strange people or situations. Additionally, researchers suggest that if parents avoid becoming too anxious, overprotective, or angry at their children's extreme fearfulness and timidity, there will be a better chance that the inhibited child will become less anxious in adolescence (Kagan, 1994).

Eric's parents followed this advice. As an infant and child, Eric (similar to left photo) showed signs of being fearful or inhibited. For example, Eric spent two weeks worrying about having to give a book report, which meant standing in front of, and speaking to, the whole class. Eric was sure he couldn't do it. His parents encouraged Eric to role-play giving his book report, so Eric repeated his speech over and over at home until he felt comfortable. When Eric gave his book report to the class, he did very well and felt great afterward (Elias, 1989). With support and understanding, parents can help a fearful child to become more outgoing and less fearful.

At the same time an infant is developing emotional behaviors, he or she is also acquiring numerous cognitive skills and abilities, which we'll discuss next.

E. Cognitive Development

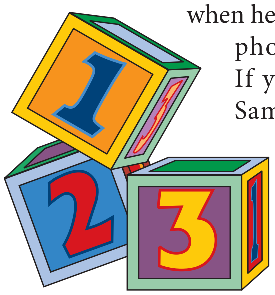
Piaget's Theory

What are blocks for?

We have explained how a newborn's brain and senses develop relatively quickly so that an infant is soon ready to creep and walk and explore and learn about a wondrous world through a process called cognitive development.

Cognitive development **refers to how a person perceives, thinks, and gains an understanding of his or her world through the interaction and influence of genetic and learned factors.**

For example, if you gave blocks to Sam, who is 5 months old (top right photo), he would surely put one into his mouth. If you gave the same blocks to Sam when he was 2 years old (bottom right photo), he might stack them. If you gave the same blocks to Sam when he was an adolescent, he might play a game of throwing them into a can. What Sam does with blocks depends on his experience and level of cognitive development.



Jean Piaget. In the history of developmental psychology, the person who had the greatest impact on the study of cognitive development was Jean Piaget, who was both a biologist and a psychologist. From the 1920s to his death in 1980, Piaget (1929) studied how children solved problems in their natural settings, such as cribs, sandboxes, and playgrounds. Piaget developed one of the most influential theories of cognitive development (Bjorklund, 2005).

Piaget believed that from early on, a child acts like a tiny scientist who is actively involved in making guesses or hypotheses about how the world works. For example, when given blocks, 5-month-old Sam puts them into his mouth, while 2-year-old Sam tries to stack them, and adolescent Sam laughs and plays a game of tossing blocks into a can. Piaget believed that children learned to understand things, such as what to do with blocks, through two active processes that he called assimilation and accommodation.

Assimilation

If you gave 5-month-old Sam a block, he would first try to put it into his mouth because at that age, infants "think" that objects are for sucking on. This mouthing behavior is an example of assimilation.

Blocks are for putting in mouth.

Assimilation **is the process by which a child uses old methods or experiences to deal with new situations.**

At 5 months, Sam will first put a new object into his mouth because his knowledge of objects is that they are for eating or sucking. Thus, Sam will assimilate the new object as something too hard to eat but all right for sucking.

Depending on their age and knowledge, children assimilate blocks in different ways: infants assimilate blocks as something to suck; toddlers assimilate blocks as something to stack or throw; adolescents assimilate blocks as something used to play games; and adults assimilate blocks as something to give to children. The assimilation of new information leads to Piaget's next process—accommodation.

Accommodation

If you gave 2-year-old Sam the same blocks, he would not try to eat them, but he might try to stack them, which is an example of accommodation.

Blocks are for stacking.

Accommodation **is the process by which a child changes old methods to deal with or adjust to new situations.**

For example, because of Sam's experience with different kinds of objects, he has learned that square, hard objects are not food but things that can be handled and stacked. Sam's learning to change existing knowledge because of new information (blocks are for stacking, not eating) is an example of accommodation, which is one way that mental growth occurs.

As an infant or child is actively involved in exploring his or her environment, there are many opportunities for assimilation and accommodation, which result in different kinds of cognitive growth and development.

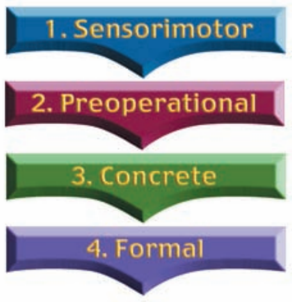
According to Piaget, children make big gains in reasoning, thinking, and understanding through active involvement and the processes of assimilation and accommodation. Using these two processes, children go through a series of cognitive stages.

Piaget's Stages of Cognitive Development

What is Sam thinking?

Piaget is best known for describing the changes or different stages in cognitive development that occur between infancy and adulthood (Bjorklund, 2005).

Piaget's cognitive stages **refer to four different stages—sensorimotor, preoperational, concrete operations, and formal operations—each of which is more advanced than the preceding stage because it involves new reasoning and thinking abilities.**



Although Piaget believed that all people go through the same four cognitive stages, he acknowledged that they may go through the stages at different rates.

Piaget's hypothesis that cognitive development occurs in stages and that each stage involves different kinds of thinking was one of his unique contributions to developmental psychology. We'll explain Piaget's four stages by following Sam through his cognitive development.

Photo Credits: both, © PhotoDisc, Inc.

1. Sensorimotor

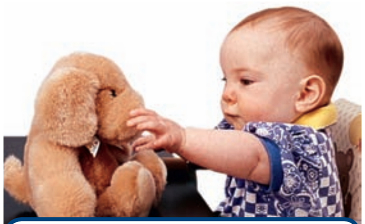
Stage 1

Imagine Sam as a newborn infant. His primary way of interacting with the world is through reflexive responses, such as sucking and grasping. By 5 months, Sam has developed enough voluntary muscle control so that he can reach out, grasp things, and put them into his mouth to discover if the things are good to suck on. Sam is in the sensorimotor stage.

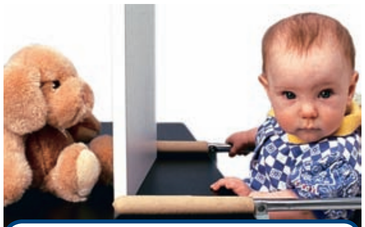
The ***sensorimotor stage*** (from birth to about age 2) is the first of Piaget's cognitive stages. During this stage, infants interact with and learn about their environments by relating their sensory experiences (such as hearing and seeing) to their motor actions (mouthing and grasping).

Hidden objects. At the beginning of the sensorimotor stage, Sam has one thinking problem: remembering that hidden objects still exist. For example, notice in the top left photo that 5-month-old Sam is shown a toy dog. Sam immediately tries to grab it and put part of it in his mouth. This is another example of assimilation; Sam believes that objects are mostly for mouthing.

However, notice in the bottom left photo that when a screen is placed in front of the dog, Sam looks away. He doesn't push the screen away to get at the toy because, at this point, Sam behaves as if things that are out of sight are out of mind and simply no longer exist. Sam has not learned object permanence.



With doggie in sight, infant tries to touch it.



With doggie hidden, infant acts as if there is no doggie.

Object permanence. Beginning at around 9 months, if Sam is shown a toy dog that is then covered by a screen, he will try to push the screen away and look for the dog. Sam has learned that a toy dog that is out of sight still exists behind the screen. This new concept is called object permanence.

Object permanence refers to the understanding that objects or events continue to exist even if they can no longer be heard, touched, or seen.

The concept of object permanence develops slowly over a period of about nine months. By the end of the sensorimotor period (about age 2), an infant will search long and hard for lost or disappeared objects, indicating a fully developed concept of object permanence.

At the end of the sensorimotor stage, 2-year-old Sam can think about things that are not present and can form simple plans for solving problems, such as searching for things.

According to Piaget, after the sensorimotor stage, Sam enters the next stage, called the preoperational stage.

2. Preoperational

Stage 2

As a 4-year-old, Sam is busy pushing a block around the floor and making noises as he pretends the block is a car. The cognitive ability to pretend is a sign that Sam is going through the preoperational stage.

The ***preoperational stage*** (from about 2 to 7 years old) is the second of Piaget's cognitive stages. During this stage, children learn to use symbols, such as words or mental images, to solve simple problems and to think or talk about things that are not present.

At this stage, Sam is acquiring the cognitive ability to pretend things and to talk about or draw things that are not physically present. Although Sam is learning to use words and images in speech and play, his thinking has a number of interesting limitations that make his thinking different from an adult's. During the preoperational stage, two of his cognitive limitations involve having problems with conservation and engaging in egocentric thinking.

Conservation. As 4-year-old Sam watches you pour milk from a tall, thin glass into a short, wide glass, will he know that the amount of milk remains the same even though its shape changes? This is called the problem of conservation.

Conservation refers to the fact that even though the shape of some object or substance is changed, the total amount remains the same.

Here's what happens when 4-year-old Sam is faced with a conservation problem.

In photo #1, 4-year-old Sam watches as his mother fills two short, wide glasses with equal amounts of milk.

In photo #2, Sam sees his mother pour the milk from one short, wide glass into a tall, thin glass. Mother asks, "Does one glass have more milk?"

In photo #3, Sam points to the tall, thin glass as having more milk because the tall glass looks larger. He makes this mistake even though he just saw his mother pour the milk from a short, wide glass.

Sam, like other children at the preoperational stage, will not be able to solve conservation problems until the next stage.

Egocentric thinking. A second problem that Sam has during the preoperational stage is that he makes mistakes or misbehaves because of egocentric thinking.

Egocentric *(ee-goh-SEN-trick)* ***thinking*** refers to seeing and thinking of the world only from your own viewpoint and having difficulty appreciating someone else's viewpoint.

Piaget used the term *egocentric thinking* to mean that preoperational children cannot see situations from another person's, such as a parent's, point of view. When they don't get their way, children may get angry or pout because their view of the world is so self-centered.

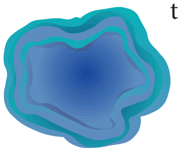
E. Cognitive Development

Stage 3

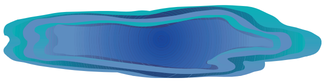
Between the ages of 7 and 11, Sam learns that even if things change their shape, they don't lose any quantity or mass, a new concept that occurs during the concrete operations stage.

The ***concrete operations stage*** (from about 7 to 11 years) is the third of Piaget's cognitive stages. During this stage, children can perform a number of logical mental operations on concrete objects (ones that are physically present).

Conservation. As you may remember, when Sam was 4 years old and in the preoperational stage, he had not mastered the concept of conservation. In the preoperational stage, Sam thought a tall, thin glass held more milk than a short, wide glass. And if 4-year-old Sam watched as a ball of clay (top left picture) was flattened into a long, thin piece (bottom left picture), he would say the long piece was larger.

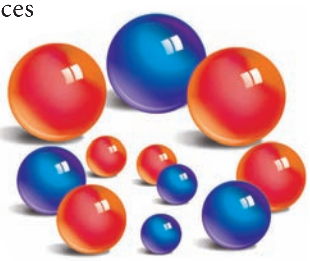


Can these two pieces of clay be the same size?



However, Sam is now 10 years old and has just watched you flatten a ball of clay into a long piece. Sam now says that the long, flattened piece contains the same amount of clay as the ball, even if the shape changed. Similarly, if 10-year-old Sam watched you pour cola from a short glass into a tall glass, he would correctly answer that the amount of cola remained the same. Children gradually master the concept of conservation during the concrete operations stage, and they also get better at classification.

Classification. If you gave a 4-year old, preoperational Sam some red and blue marbles in different sizes (picture below), he would be able to classify the pieces according to a single category, such as size. However, during the concrete operations stage, 10-year-old Sam has acquired the ability to classify the marbles according to two categories, such as color and size, indicating that he has learned a new cognitive skill.



During the concrete stage, children learn to sort objects by both size and color.

New abilities. During the concrete operations stage, children learn to classify or sort objects according to more than one category, and they learn to solve a variety of conservation problems. The reason Piaget called this the *concrete* operations stage is that children can easily classify or figure out relationships between objects provided the objects are actually physically present or "concrete."

However, children at the concrete operations stage still have difficulty figuring out relationships among objects that are not present or situations that are imaginary. Thinking about imaginary or hypothetical situations occurs in Piaget's fourth stage.

Stage 4

Sam is now 17 years old and is surfing the Web for a paper he's writing on what killed the dinosaurs. This kind of abstract thinking indicates that Sam is in the formal operations stage.

The ***formal operations stage*** (from about 12 years old through adulthood) is Piaget's fourth cognitive stage. During this stage, adolescents and adults develop the ability to think about and solve abstract problems in a logical manner.

Piaget believed adolescents develop thinking and reasoning typical of adults during the formal operations stage. For example, 17-year-old Sam can compare theories about why the dinosaurs died, including being destroyed by a giant asteroid, radical temperature change, or some terrible virus. During this stage, adolescents also encounter new worlds of abstract ideas and hypothetical concepts. For example, Sam can discuss abstract ideas, such as whether computer hackers should go to jail, if going steady is a good idea, and how strict parents should be.

Acquiring the ability to think in a logical, systematic, and abstract way is one of the major characteristics of the formal operations stage. In comparison, seven years ago, when Sam was in the concrete operations stage, he lacked the ability to solve abstract problems. As you may have already realized, the cognitive skills associated with the formal operations stage are the very ones you need to do well in college.

How much does the thinking of a 17-year-old differ from that of a 10-year-old?

Along with advances in cognitive abilities, the formal operations stage welcomes the return of ***egocentric thinking,*** which refers to the tendency of adolescents to believe that others are always watching and evaluating them, and the belief that everyone thinks and cares about the same things they do. Because adolescents think people are watching their every move, they act as though they are performing in front of an audience. Of course, such an audience doesn't really exist because everyone is not actually obsessed with the teen's every action. Thus, this phenomenon is named the imaginary audience.

Imaginary audience refers to the belief adolescents have that everyone is watching all of their actions.

I think everyone is always watching me.

Another aspect of adolescent thinking related to egocentric thinking is the personal fable.

Personal fable refers to an adolescent's belief that he or she is invulnerable, unique, and special.

This type of thinking explains why adolescents can never accept that anyone might even remotely understand how they are feeling, because after all they are unique and special (Elkind, 1967, 1998).

Evaluation of Piaget's Theory

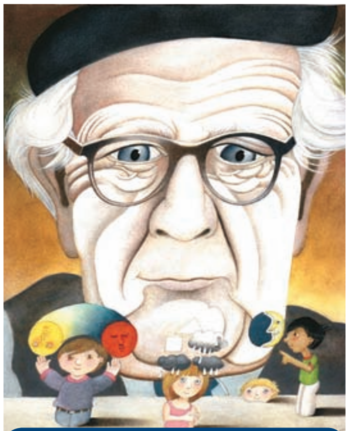
What's happened to Piaget's theory?

We have discussed Piaget's cognitive stages in some detail, but there are three ideas that stand out (Larivee et al., 2000): (1) Children gradually and in a step-by-step fashion develop reasoning abilities through the active processes of assimilation and accommodation. (2) Children are naturally curious and self-motivated to explore their worlds and, in the process, develop numerous cognitive skills. (3) Children acquire different kinds of thinking and reasoning abilities as they go through different stages of cognitive development.

Piaget's theory has had a tremendous influence on the area of cognitive development. However, over the past 50 years, there have been numerous criticisms of Piaget's theory. We'll discuss these criticisms along with current ideas about cognitive development.

Impact and Criticisms

Impact of Piaget's theory. For three main reasons, Piaget's theory has had a huge impact on understanding cognitive development. First, his theory was far more comprehensive than any other theory at the time. Second, his theory triggered an enormous amount of research and led to the development of other cognitive development theories. Third, many of Piaget's ideas have proven correct and have been replicated (R. J. Sternberg et al., 2003b).



Jean Piaget (1896–1980)

Criticisms. There are three main criticisms. First, Piaget's four stages are not as rigid or orderly as he proposed. For example, children can solve certain kinds of problems at stages earlier than Piaget proposed (e.g., some babies as young as 10 weeks understand object permanence) (S. Wang et al., 2005). Because children do show certain thinking skills earlier than would be predicted from Piaget's cognitive stages, his four stages are now seen as not being as rigid or orderly as he initially proposed (R. J. Sternberg et al., 2003b).

Second, although Piaget described how children can and cannot think at different ages and stages, his theory is criticized for not explaining how or why this change occurs (Bruner, 1997). Today, researchers associate changes in thinking with changes in the brain, something unknown to Piaget (Petrill, 2003).

Third, children failed some of the Piagetian tasks not because children lacked the thinking abilities but because they did not understand the instructions. For example, preoperational children can solve some abstract problems, such as who is taller or shorter than someone else, provided the problems are presented simply. According to Piaget, preoperational children should not be able to solve these simple abstract problems.

Current status. Almost by himself, Piaget began the area of cognitive development. His observational methods to study children and his view that children are active explorers in discovering their worlds are still considered important ideas. However, because of criticisms and new findings on the influence of genetic and neural factors, Piaget's theory is now viewed as having historical importance but is no longer the major force in guiding research in cognitive development (Newcombe, 2002).

New Information

Since Piaget developed his theory, there have been two major changes in understanding and studying cognitive development.

1 Genetic factors. One of the biggest changes has involved identifying genetic factors that influence many cognitive abilities. For example, research on identical and fraternal twins shows that genetic factors account for 20% to 60% of the influence on verbal, spatial, and perceptual abilities (Petrill, 2003). In Piaget's time, the influence of genetic factors on cognitive abilities had not been as clearly established.

Recently, there has been an increasing number of studies showing how genetic factors (nature) interact with a child's environmental and learning experiences (nurture) in the development of cognitive abilities. For example, being outgoing and fearless is related to the kind of temperament an infant inherits (nature) (Kagan, 2003a). Researchers reported that children who had been rated high in seeking stimulation at age 3 scored significantly higher on IQ tests at age 11 compared to children who had been rated low in seeking stimulation at age 3. This significant difference in IQ scores (11 points) was not related to the occupation or education of their parents. Researchers concluded that children rated high in seeking stimulation (nature) were more curious and open to learning from their environments (nurture), which in turn enhanced the development of their cognitive abilities and resulted in higher scores on IQ tests (A. Raine et al., 2002). Researchers conclude that genetic factors set a range for many cognitive abilities and these abilities can be either facilitated by a stimulating environment or depressed by an impoverished environment (Bjorklund, 2005).

2 Brain development. Another major change has been our knowledge of how the brain develops. After birth and continuing through adolescence, different areas of the brain develop at different times. For example, the infant on the right doesn't know the doggie is hidden behind the screen because his prefrontal cortex is not yet well developed (Kalat, 2009). Similarly, at about age 2, a child learns on average a new word every two hours, in large part because of rapid neural growth in the brain's language areas (Pinker, 1994). These kinds of studies point out that cognitive development results from the interaction among genetic, neural, and environmental factors, much of which was unknown during Piaget's time.

Child fails to find the doggie because his prefrontal cortex is not well developed.

Cognitive development is closely intertwined with and occurs at the same time as social development, which we'll examine next.

F. Social Development

What will happen to Alex?

At the beginning of this module we described how Alex was raised in an orphanage until age 3, at which time he was adopted. Some psychologists wonder how Alex's early emotional difficulties will affect his future social development.

Social development refers to how a person develops a sense of self or a self-identity, develops relationships with others, and develops the kinds of social skills important in personal interactions.

After Alex was adopted, we know that even after a few years with his adoptive parents he never seemed to have made a good adjustment. Some psychologists would not be surprised that Alex never developed close relationships with others or that he never learned social skills important in personal interactions. This is because some psychologists believe the first five years are the most important and that early emotional troubles may lead to later social problems.

Alex's social development is a long and complicated process, which is influenced by many of the emotional and cognitive factors that we have just discussed. We'll describe three different theories of social development, each of which emphasizes a different aspect of behavior.

Freud's Psychosexual Stages

One of the best-known theories is that of Sigmund Freud (1940/1961), who said that each of us goes through five successive psychosexual stages.

The ***psychosexual stages*** are five different developmental periods—oral, anal, phallic, latency, and genital stages—during which the individual seeks pleasure from different areas of the body that are associated with sexual feelings. Freud emphasized that a child's first five years were most important to social and personality development.

Does an infant's experience during breast feeding have lasting effects?

In Freud's theory, there is often conflict between the child and parent. The conflict arises because the child wants immediate satisfaction or gratification of its needs, while the parents often place restrictions on when, where, and how the child's needs should be satisfied. For example, a child may wish to be fed immediately, while the parent may want to delay the feeding to a more convenient time. Freud believed that interactions between parent and child in satisfying these psychosexual needs—for example, during breast feeding or toilet training—greatly influence the child's social development and future social interactions. In addition, Freud emphasized the importance of a child's first five years in influencing future social development or future personality problems.

According to Freud, Alex will go through five developmental stages, some of which contain potential conflicts between his desires and his parents' wishes. If his desires are over- or undersatisfied, he may become fixated at one of the first three stages. As you'll see, becoming fixated at one of these stages will hinder his normal social development.

1 Oral Stage

Period: Early infancy—first 18 months of life.

Potential conflict:

The ***oral stage*** lasts for the first 18 months of life and is a time when the infant's pleasure seeking is centered on the mouth.

Pleasure-seeking activities include sucking, chewing, and biting. If Alex were locked into or fixated at this stage because his oral wishes were gratified too much or too little, he would continue to seek oral gratification as an adult.

2 Anal Stage

Period: Early infancy—1½ to 3 years.

Potential conflict:

The ***anal stage*** lasts from the age of about 1½ to 3 and is a time when the infant's pleasure seeking is centered on the anus and its functions of elimination.

If Alex were locked into or fixated at this stage, he would continue to engage in behavioral activities related to retention or elimination. Retention may take the form of being very neat, stingy, or behaviorally rigid. Elimination may take the form of being generous or messy.

3 Phallic Stage

Period: Early childhood—3 to 6 years.

Potential conflict:

The ***phallic (FAL-ick) stage*** lasts from about age 3 to 6 and is a time when the infant's pleasure seeking is centered on the genitals.

During this stage, Alex will compete with the parent of the same sex (his father) for the affections and pleasures of the parent of the opposite sex (his mother). Problems in resolving this competition (called the Oedipus complex and discussed in Module 19) may result in Alex going through life trying to prove his toughness.

4 Latency Stage

Period: Middle and late childhood—from 6 to puberty.

The ***latency stage,*** which lasts from about age 6 to puberty, is a time when the child represses sexual thoughts and engages in nonsexual activities, such as developing social and intellectual skills.

At puberty, sexuality reappears and marks the beginning of a new stage.

5 Genital Stage

Period: Puberty through adulthood.

The ***genital stage*** lasts from puberty through adulthood and is a time when the individual has renewed sexual desires that he or she seeks to fulfill through relationships with members of the opposite sex.

If Alex successfully resolved conflicts in the first three stages, he will have the energy to develop loving relationships and a healthy and mature personality.

According to Freud, Alex's future personality and social development will depend, to a large extent, on what he experiences during the first three psychosexual stages, which occur during his first five years. Freud's psychosexual stages are part of his larger psychoanalytic theory of personality, which we'll discuss more fully in Module 19.

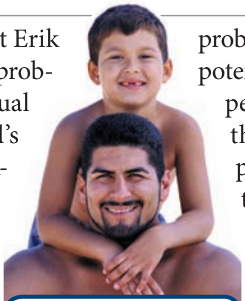
Photo Credit: © PhotoDisc, Inc.

Erikson's Psychosocial Stages

How important is trust?

According to well-known psychologist Erik Erikson, Alex will encounter kinds of problems very different from the psychosexual ones proposed by Freud. Unlike Freud's emphasis on psychosexual issues, Erikson (1963, 1982) focused on psychosocial issues and said that each of us goes through eight psychosocial stages.

The ***psychosocial stages*** are eight developmental periods during which an individual's primary goal is to satisfy desires associated with social needs. The eight periods are associated, respectively, with issues of trust, autonomy, initiative, industry, identity, intimacy, generativity, and ego integrity.



Are the effects of psychosocial problems long-lasting?

Erikson hypothesized that from infancy through adulthood we proceed through these stages, each of which is related to a different problem that needs to be resolved. If we successfully deal with the potential problem of each psychosocial stage, we develop positive personality traits and are better able to solve the problem at the next stage. However, if we do not successfully handle the psychosocial problems, we may become anxious, worried, or troubled and develop social or personality problems.

Unlike Freud, Erikson believed that psychosocial needs deserve the greatest emphasis and that social development continues throughout one's lifetime. Thus, Erikson would emphasize Alex's psychosocial needs and downplay the importance of sexuality in the first five years.

We'll explain Erikson's first five stages here and discuss the remaining three stages in Module 18, which deals with social development in adolescents and adults.

Stage 1 Trust versus Mistrust

Period: Early infancy—birth through first year.

Potential problem: Alex comes into the world as a helpless infant who needs much care and attention. If his parents are responsive and sensitive to his needs, Alex will develop what Erikson calls basic trust, which makes it easier for him to trust people later in life. If Alex's parents neglect his needs, he may view his world as uncaring, learn to become mistrustful, and have difficulty dealing with the second stage. It appears that Alex did not receive the care and attention he needed during his first year of life.

Stage 2 Autonomy versus Shame and Doubt

Period: Late infancy—1 to 3 years.

Potential problem: As Alex begins walking, talking, and exploring, he is bound to get into conflict with the wishes of his parents. Thus, this second stage is a battle of wills between his parents' wishes and Alex's desires to do as he pleases. If his parents encourage Alex to explore, he will develop a sense of independence, or autonomy. If his parents disapprove of or punish Alex's explorations, he may develop a feeling that independence is bad and feel shame and doubt.

Stage 3 Initiative versus Guilt

Period: Early childhood—3 to 5 years.

Potential problem: As a preschooler, Alex has developed a number of cognitive and social skills that he is expected to use to meet the challenges in his small world. Some of these challenges involve assuming responsibility and making plans. If his parents encourage initiative, Alex will develop the ability to plan and initiate new things. However, if they discourage initiative, he may feel uncomfortable or guilty and may develop a feeling of being unable to plan his future.

Stage 4 Industry versus Inferiority

Period: Middle and late childhood—5 to 12 years.

Potential problem: Alex's grade school years are an exciting time, filled with participating in school, playing games with other children, and working to complete projects. If Alex can direct his energy into working at and completing tasks, he will develop a feeling of industry. If he has difficulty applying himself and completing homework, he may develop a feeling of inferiority and incompetence.

Stage 5 Identity versus Role Confusion

Period: Adolescence.

Potential problem: Adolescents need to leave behind the carefree, irresponsible, and impulsive behaviors of childhood and develop the more purposeful, responsible, planned behaviors of adults. If Alex is successful in making this change, he will develop a sense of confidence and a positive identity. If he is unsuccessful, he will experience role confusion, which will result in having low self-esteem and becoming socially withdrawn.

According to Erikson, Alex will encounter a particular psychosocial problem at each stage. If he successfully solves the problem, he will develop positive social traits that will help him solve the next problem. If he does not solve the problem, he will develop negative social traits that will hinder his solving a new problem at the next stage.

Evaluation of Erikson's and Freud's theories. Many psychologists agree with Erikson that psychosocial conflicts do contribute to social-emotional development (Bugental & Goodnow, 1998). Erikson said that the first five years were not necessarily the most important and that social development continues throughout one's life. In fact, longitudinal studies show that personality change and development continue well into middle adulthood (Erber, 2005).

Many psychologists also agree with Freud that childhood events are important to social development (Guterl, 2002; Sigelman & Rider, 2006). However, they criticize Freud for emphasizing childhood sexuality while neglecting the influences of social and cognitive factors on social development (Bugental & Goodnow, 1998). In addition, longitudinal studies show that children may overcome a variety of problems during the first five years and still have a well-adjusted personality, contrary to Freud's predictions (E. E. Werner, 1995).

The strength of Erikson's and Freud's theories is that they explain the whole of social development, from infancy through adulthood. Their weakness is that many of their concepts (trust, autonomy, oral stage, fixation) are more descriptive than explanatory and are difficult to verify or test experimentally (Austrian, 2002). Next, we'll examine the social cognitive theory of social development.

F. Social Development

Bandura's Social Cognitive Theory

What is the 3-year-old doing?

After watching his daddy bowl, this 3-year-old boy walked up to his daddy, pointed at the ball, and said, "Me too ball." Neither Freud's nor Erikson's theory explains why this boy wanted to learn to bowl, what motivated him to ask his daddy, or why he clapped his hands just like his daddy when the ball hit the pins. Albert Bandura (2001a) says that this little boy, like all of us, develops many of his behaviors and social skills through a variety of social cognitive processes.

The ***social cognitive theory*** **emphasizes the importance of learning through observation, imitation, and self-reward in the development of social skills, interactions, and behaviors. According to this theory, it is not necessary that you perform any observable behaviors or receive any external rewards to learn new social skills because many of your behaviors are self-motivated, or intrinsic.**

He watched his daddy bowl and then he wanted to.

Social cognitive theory stresses how you learn by modeling and imitating behaviors you observe in social interactions and situations. For example, after watching his daddy, this boy is intrinsically motivated to imitate many of his daddy's social behaviors. Social cognitive theory emphasizes that children develop social behaviors and skills by watching and imitating the social behaviors of their parents, teachers, and peers.

In comparing Bandura's, Freud's, and Erikson's theories, we notice that although the three theories are very different, they are complementary because each emphasizes a different process. Social cognitive theory emphasizes learning through modeling; Freud's theory focuses on parent–child interactions that occur in satisfying innate biological needs; and Erikson's theory points to the importance of dealing with social needs.

We'll use these theories to explain how some children overcame terrible childhood experiences to develop normal social behaviors.

Resiliency

How do children overcome early problems?

Based on observations of his patients, Freud concluded that social and personality development is essentially completed in the first five years. That is, even though an individual might undergo later social changes, his or her basic social and personality traits are primarily established during the first five years. One way to test Freud's hypothesis is to do a long-term study of children who are faced with major problems. One such individual is Dave Pelzer.

Beginning in his early childhood, Dave's extremely disturbed, alcoholic mother did her best to put him through one life-threatening situation after another. She abused him mentally, physically, and emotionally. Some of the ways she tortured him were by denying him food, clothing, and warmth, forcing him to drink ammonia, stabbing him in his stomach, and constantly threatening to kill him. She belittled Dave by referring to him only as "It" rather than his name. Dave's father and brothers (who were not abused) did nothing to stop the horrendous abuse.

Dave had to do everything he could to survive. He stole food to eat as his mother aimed to starve him to death. When his mother burned him or stabbed him, he would take care of his wounds while in agonizing pain. The abuse Dave endured was so grave that it has been identified as one of the most serious and disturbing cases of child abuse on record.

At age 12, Dave was finally removed from his mother's custody and placed in several foster homes. He struggled to adjust to these various caregivers, but he finally developed a trusting, loving relationship with two caregivers he learned to call Mom and Dad.

Dave was exposed to very serious life stressors during his childhood. How these stressors affect children depends on each child's vulnerability and resiliency.

Dave Pelzer overcame a truly disturbing childhood because of his incredible resilience.

Vulnerability **refers to psychological or environmental difficulties that make children more at risk for developing later personality, behavioral, or social problems.**

Resiliency **refers to various personality, family, or environmental factors that compensate for increased life stresses so that expected problems do not develop.**

There is no question that Dave was extremely vulnerable. Although other children with such high vulnerability may have later developed very serious emotional or behavioral problems, Dave triumphed over seemingly insurmountable odds, displaying tremendous resiliency, and developed into a competent, courageous, and autonomous adult. He served as a member of the armed forces, where his accomplishments earned him personal commendations by three former U.S. presidents. Dave has authored six best-selling inspirational books, two of which were nominated for the Pulitzer Prize. And, given the passion that drives him, Dave's contributions to this world are far from over.

Children like Dave are called resilient, or stress-resistant. These children defy expectations because they develop into well-adapted individuals despite serious life stressors (Gorman, 2005a). For example, even though Dave experienced a severely brutal childhood, he developed into an amazing individual with high achievement motivation and much insight into his life (Peltzer, 1995, 1997, 1999, 2000, 2003, 2009).

Studies on resilient children show three findings. First, early traumatic events do not necessarily lead to later social-emotional problems, as Freud predicted. Second, a loving, supportive caregiver or teacher can substitute for a disinterested parent. Third, children observe and imitate normal social behaviors modeled by caregivers (R. Brooks & Goldstein, 2002; E. E. Werner & Smith, 2001). We'll use these theories to explain how some children overcame terrible childhood experiences to develop normal social behaviors.

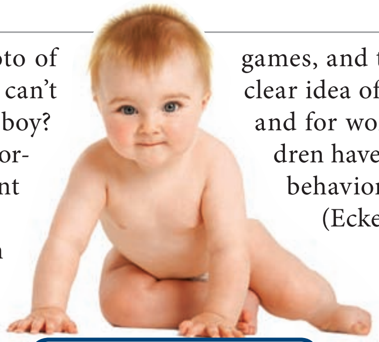
Gender Differences

What three words change your life forever?

When you look at the photo of the infant on the right, you can't help asking, Is it a girl or a boy? This question has great importance to social development because it involves gender identity.



By age 3, this infant will know which sex he or she is.

Gender identity. By the age of 3, most children learn to label themselves as boys or girls and can classify others as being the same sex or the other sex (Ruble et al., 2006).

Gender identity refers to the individual's subjective experience and feelings of being a female or male.

Once children know their correct sex, they begin to learn and show sex-appropriate behaviors, which are called gender roles.

Gender roles. By ages 2 to 3, American children have learned the preference of each traditional gender role for toys, clothes, games, and tools. By ages 4 to 5, children have developed a clear idea of which occupations are stereotypically for men and for women. And by the relatively early age of 5, children have already learned the thoughts, expectations, and behaviors that accompany their particular gender roles (Eckes & Trautner, 2000).

Gender roles are the traditional or stereotypical behaviors, attitudes, and personality traits that parents, peers, and society expect us to have because we are male or female.

Gender roles become part of who we are and have a relatively powerful effect on how we behave, think, and act.

How children acquire gender roles is explained by two somewhat different but related theories: social role theory and cognitive developmental theory (C. L. Martin et al., 2002).

Social Role Theory

In many families, the parents expect a son to behave and act differently than a daughter. How parental expectations influence a child's gender identity is explained by the social role theory (Eagly et al., 2000).

The ***social role theory*** emphasizes the influence of social and cognitive processes on how we interpret, organize, and use information. Applied to gender roles, it says that mothers, fathers, teachers, grandparents, friends, and peers expect, respond to, and reward different behaviors in boys than in girls. Under the influence of this differential treatment, boys learn a gender role that is different from girls'.

For example, the stereotypical gender roles for males include being dominant, controlling, and independent, while gender roles for females include being sensitive, nurturing, and concerned (Eagly & Karau, 2002; W. Wood et al., 1997). According to social role theory, these gender differences originate, to a large extent, because mothers and fathers respond to and reward different behaviors in girls than in boys.

Why does she want to be a model?

For instance, in playing with boys, fathers were observed to model being assertive and dominant, while in playing with girls, mothers were observed to model being concerned and nurturing (Leaper, 2000). Mothers were found to be more likely to enforce rules when their daughters misbehaved in a way that might be dangerous than when their sons misbehaved in a similar way (Morrongiello & Hogg, 2004). Parents are more likely to encourage dependence in girls, reward boys for conforming to traditional play activities, and reward girls for doing traditional household chores (Keenan & Shaw, 1997). These differences in parents' behaviors support the social role theory idea that parents encourage or discourage behaviors depending on whether these behaviors match traditional boy–girl gender roles.

One criticism of social role theory is that it focuses too much on rewarding and discouraging behaviors and too little on cognitive influences, which are emphasized in the cognitive developmental theory.

Cognitive Developmental Theory

When you were a child, you probably learned that there were ways or rules about what boys and girls could and could not do. This childhood experience supports the cognitive developmental theory (C. L. Martin, 2000).

The ***cognitive developmental theory*** says that, as children develop mental skills and interact with their environments, they learn one set of rules for male behaviors and another set of rules for female behaviors.

In this view, children actively process information that results in their learning gender rules regarding which behaviors are correct for girls and wrong for boys, and vice versa. On the basis of these rules, children form mental images of how they should act; these images are called gender schemas.

Why does he want to be a baseball player?

Gender schemas are sets of information and rules organized around how either a male or a female should think and behave (S. L. Bem, 1985).

For instance, the traditional gender schema for being a boy includes engaging in rough-and-tumble play and sports, initiating conversations, and exploring; the traditional gender schema for being a girl includes playing with dolls, expressing emotions, listening, and being dependent.

Cognitive developmental theory emphasizes that a child is an active participant in learning a male or female set of rules and schemas, which result in different gender roles (S. L. Bem, 1981).

Both social role theory and cognitive developmental theory predict that the sexes will develop different gender roles.

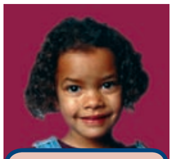
F. Social Development

Differences in Gender Traits



CONCERNED
SENSITIVE
NURTURING

Girls and boys develop very different gender roles. For example, girls develop traits of being concerned, sensitive, and nurturing (left figure), while boys develop traits of being independent, controlling, and dominant (right figure) (Eckes & Trautner, 2000). These differences in gender traits are explained by two different theories.

According to **social role theory,** the expectations of parents, peers, and others ***reward*** or ***discourage*** different gender roles and behaviors for boys and girls. Social role theory focuses on boys and girls learning different gender roles and behavior because of ***outside pressures*** from family, peers, and society.

INDEPENDENT
CONTROLLING
DOMINANT

According to **cognitive developmental theory,** children acquire gender schemas or ***cognitive rules*** that indicate which gender roles and behaviors are right or wrong for boys and girls. Cognitive developmental theory focuses on boys and girls developing different gender roles because of ***inside pressures,*** which come from their own personal rules.

These two theories are not mutually exclusive but rather emphasize different factors in the development of gender-role differences and behaviors (C. L. Martin et al., 2002).

We'll discuss how differences in gender traits have important influences on personal, social, and career choices.

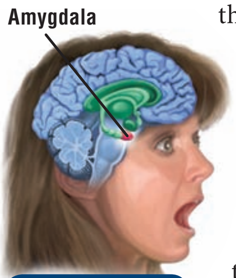
Male and Female Differences

Can a woman be elected president?

Career choices. As boys and girls grow into men and women, their different gender roles, which involve different ways for men and women to think, behave, interact socially, and make career choices, are further strengthened by pressures from parents, peers, and society (Eckes & Trautner, 2000). For example, until the early 1990s, gender roles for women did not include careers in law enforcement, armed forces, fire or police departments, or management of large corporations, while gender roles for men did not include careers as nurses, secretaries, or elementary-school teachers. Since then gender roles have changed so that men and especially women have more flexibility and freedom in making job and career choices. However, gender roles still influence career choices, the most obvious being the reluctance to elect a woman as president of the United States.

Boys and men are more aggressive.

Aggression. Researchers find that, from the age of 2 through college age, males tend to show more rough-and-tumble play, display more aggressive physical and verbal behavior, and commit more violent crimes than females (Kenrick et al., 2004). Sex differences in physical aggression have been found in children as young as 17 months. For example, one study found 17-month-old boys were twice as likely as girls to hit another child frequently (Baillargeon, 2002). Twin and adoption studies indicate the reasons for these sex differences in aggressive behavior include both genetic and environmental factors (Perusse & Gendreau, 2005). Therefore, while biological factors help to explain why boys are more aggressive than girls, psychosocial influences also play a key role. For example, researchers found that parents, peers, and society reward boys for acting out, being competitive, and settling their conflicts with fighting. In comparison, "nice girls" don't fight and tend to settle conflicts through talking (Coie & Dodge, 1998). As a result of these biological and psychosocial influences, the gender role for males encourages aggressive behavior and helps explain why the majority of aggressive acts, both social and criminal, are committed by males (DiLalla, 2002; D. F. Halpern, 2000).



Women had more activation of brain areas.

Different brains. One reason girls and women develop traits of being concerned, sensitive, and nurturing may involve how women's brains process emotional situations. For example, researchers took brain scans (fMRI) while women and men looked at photos, which they graded from neutral (bookcase, landscape) to emotionally intense (crying people, dead body). Weeks later, when the subjects were asked to pick out photos that they had earlier rated as emotionally intense, women correctly remembered 10–15% more than men did. Equally interesting, brain scans taken during viewing of the emotionally intense photos indicated that in women's brains the amygdala and additional areas were more activated than in men's brains. Researchers concluded that, compared to men, women's brains are more effectively wired for processing, coding, and remembering emotional experiences. Researchers suggested that women's greater focus on emotional events may help explain why women report higher rates of clinical depression than men (Canli et al., 2002). These findings also support the evolutionary theory of behavior, which says that in early times women developed particular emotional traits, such as being concerned, sensitive, and nurturing, because these traits were beneficial to women in maintaining a stable family structure and in raising children (Caporael, 2001).

Another gender difference in brain functions is that women process language by using both sides of their brains, while men use only the left side (Clements et al., 2006). This difference may explain why women are generally better at processing words and performing language tasks (D. F. Halpern, 2000).

Conclusion. No amount of brain research will explain all the social differences between males and females. Many other factors, such as temperament, attachment, family background, and environment, may explain why the sexes can be so different (Tyre, 2006). Sex differences in brain function do not mean that one brain is better; any difference found should not be used as the basis for discrimination (Galliano, 2003; L. Rogers, 2001).

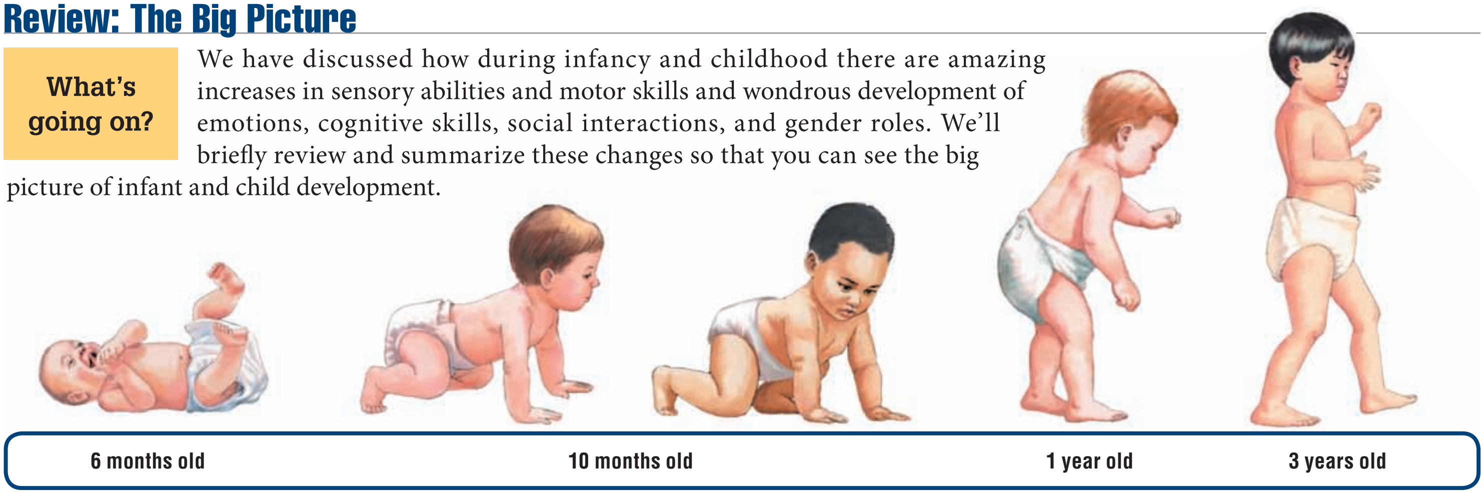
Review: The Big Picture

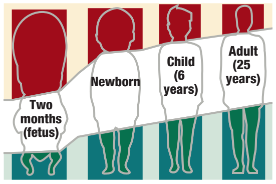
What's going on? We have discussed how during infancy and childhood there are amazing increases in sensory abilities and motor skills and wondrous development of emotions, cognitive skills, social interactions, and gender roles. We'll briefly review and summarize these changes so that you can see the big picture of infant and child development.



1 Newborns' Abilities

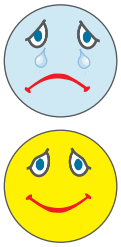
Newborns come with more sensory and perceptual abilities than previously thought. They have a well-developed sense of touch, show an innate preference for sweet and salt, and recognize (smell) their mothers' odors. In a few more months, infants can recognize their mothers' faces, produce speech sounds, and perceive depth. This new and improved version of infants' abilities better explains how they discover the world.

2 Motor Development



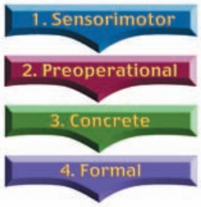
Infants gradually acquire the ***coordinated movements*** that they need to crawl, sit, stand, and walk. Many motor skills occur in a set sequence called ***maturation*** that is regulated by genetic programming. Two principles for motor development are that parts closest to the center of the body develop first—the ***proximodistal*** principle—and parts closer to the head develop first—the ***cephalocaudal*** principle. With motor development comes the ability to get up and explore.

3 Emotional Development



"Good" babies and "difficult" babies show signs of differences in temperament, which is largely influenced by genetic factors. ***Temperament*** refers to stable differences in attention, arousal, and reaction to new situations; it also affects level of arousal and the development of emotional behaviors. Infants develop many ***emotions,*** which allow a wide range of wordless communications with the parent and the world. Infants form a close emotional bond with parents (caregivers). This emotional bond, which is called ***attachment,*** is thought to influence the development of future emotional and social behaviors.

4 Cognitive Development



One theory of cognitive development is ***Piaget's theory,*** which says that children play an active role in cognitive development by incorporating new information into existing knowledge ***(assimilation)*** or changing existing knowledge through experience ***(accommodation).*** Children pass through four different cognitive stages—***(1) sensorimotor, (2) preoperational, (3) concrete operations,*** and ***(4) formal operations***—in that order but at different rates. With each stage, the child adds a new and qualitatively different kind of thinking or reasoning skill that helps the child make better sense of the world.

5 Social Development

At the same time that children are developing emotionally and cognitively, they are also developing socially. ***Freud*** said that children develop socially by going through five ***psychosexual stages*** and that during the first three stages, the individual seeks pleasure from different areas of the body associated with sexual feelings. Freud's is the only theory that says the first five years are critical. ***Erikson*** said that children develop socially by going through eight ***psychosocial stages*** during which an individual's primary goal is to satisfy desires associated with social needs. According to ***Bandura's social cognitive theory,*** children develop social skills through imitation, observation, and self-reward. These three theories are not mutually exclusive but rather complement each other by focusing on different factors believed to be important in social development.

6 Importance of Childhood

Oliviero Toscani for BENETTON

How important are events that occur during childhood? In some cases, traumatic events (poverty, parental disinterest) result in later behavioral and social problems, but in other cases, a loving, supportive parent or caregiver compensates for early problems, which results in a resilient child. Although childhood may be an important time for emotional, social, and personality development, both positive and negative personality and social changes continue into middle adulthood.

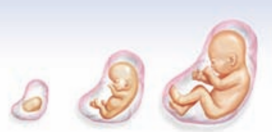
After the Concept Review, we'll examine an interesting and related question: Do children from very different cultures acquire similar or different gender roles and behaviors?

Photo Credits: center left and right, © PhotoDisc, Inc.; bottom right, © Oliviero Toscani for BENETTON

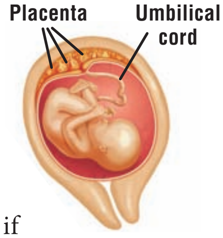
Concept Review

1. The question that asks how much genetic factors and how much environmental factors contribute to a person's biological, emotional, cognitive, personal, and social development is called the __________ question.

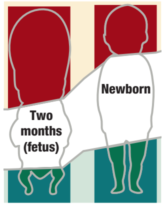
2. The prenatal period, which begins at conception and ends at birth, is composed of three different stages. The first stage of prenatal development refers to the two-week period following conception; this is called the (a) __________ stage. The second stage of the prenatal period spans the 2–8 weeks that follow conception; this is called the (b) __________ stage. The third stage of the prenatal period begins two months after conception and lasts until birth; this is called the (c) __________ stage.



3. The organ that connects the blood supply of the mother to that of the fetus is called the (a) __________, which acts as a filter. However, some agents, such as drugs, viruses, and chemicals, pass into the fetal blood supply and harm the developing fetus; these agents are called (b) __________. One example of these agents is alcohol, which if drunk heavily by the mother during pregnancy can result in a combination of physical changes and mental retardation in the baby called (c) __________.



4. Newborns have some visual acuity, respond to touch, and are able to hear, smell, and taste. This indicates that they have relatively well-developed __________.



5. The acquisition of the muscular control necessary for coordinated physical activity, which is called (a) __________ development, follows two general principles. The principle that parts of the body closer to the head develop before parts closer to the feet is the (b) __________ principle. The principle that parts closer to the center of the infant's body develop before parts farther away is the (c) __________ principle. Development of motor skills occurs in a sequential and orderly fashion because of a genetic plan; this process is called (d) __________.

6. An individual's stable pattern of behavioral and emotional reactions that appear early and are influenced in large part by genetic factors is called his or her __________.

7. The close fundamental emotional bond that develops between the infant and his or her parent or caregiver is called (a) __________. Infants who use their parent as a safe home base from which they can wander off and explore their environments are said to have formed a (b) __________ attachment. Infants who avoid or show ambivalence toward their parents are said to have formed an (c) __________ attachment.

8. Piaget believed that children are actively involved in understanding their world through two basic processes: incorporating new information or experience into existing knowledge is called (a) __________; changing existing knowledge or experience as a result of assimilating some new information is called (b) __________.

9. Piaget's theory of cognitive development includes four stages, each of which is characterized by the development of particular kinds of reasoning. The first stage, during which infants learn about their environments by relating their sensory experiences (such as hearing and seeing) to their motor actions, is called the (a) __________ stage. The second stage, during which infants learn to use symbols to think about things that are not present and to help them solve simple problems, is called the (b) __________ stage. The third stage, during which children learn to perform a number of logical mental operations on objects that are physically present, is called the (c) __________ stage. The fourth stage, during which adolescents and adults develop the ability to think about and solve abstract problems in a logical manner, is called the (d) __________ stage.

10. According to Freud's theory of social development, children go through five developmental periods, which he called __________ stages. During these stages, a child's primary goal is to satisfy desires associated with innate biological needs.

11. According to Albert Bandura's social cognitive theory, we learn social skills through __________, __________, and self–reward.

12. According to Erik Erikson, a person goes through eight developmental periods during which the primary goal is to satisfy desires associated with social needs. Each of these eight periods is called a __________ stage, during which the person works to resolve a potential problem.

Answers: 1. nature-nurture; 2. (a) germinal, (b) embryonic, (c) fetal; 3. (a) placenta, (b) teratogens, (c) fetal alcohol syndrome; 4. senses; 5. (a) motor, (b) cephalocaudal, (c) proximodistal, (d) maturation; 6. temperament; 7. (a) attachment, (b) secure, (c) insecure; 8. (a) assimilation, (b) accommodation; 9. (a) sensorimotor, (b) preoperational, (c) concrete operations, (d) formal operations; 10. psychosexual; 11. observation, imitation; 12. psychosocial

G. Cultural Diversity: Gender Roles

Identifying Gender Roles

Do cultures have different gender roles?

Although we know that young boys and girls acquire different gender roles, the intriguing question is, Why do little boys generally grow up to be more aggressive and independent, while little girls grow up to be less aggressive and more nurturing? To answer this question, researchers tested hundreds of 5-, 8-, and 11-year-old children in 24 countries to find out if young children from so many different cultures developed similar or different male–female gender roles and behaviors (J. E. Williams & Best, 1990).

For younger children (5- and 8-year-olds), researchers told 32 brief stories and then asked whether the person in the story was more like a man or a woman; an example is given on the left. For older children (11-year-olds), researchers gave a list of 300 adjectives, such as aggressive, affectionate, calm, bossy, sensitive, loud, and helpful, and asked which adjectives were more likely to be associated with men and which with women. Unlike 5- and 8-year-old children, 11-year-olds were able to understand the meanings of the adjectives and indicate their choices by checking off adjectives that they thought best suited men or women.

One of these people is a very affectionate person. When they like someone, they hug and kiss them a lot. Which person likes to hug and kiss a lot?

Gender Roles across Cultures

Similarities. Researchers found that across the 24 countries, relatively young children showed remarkable similarities in the characteristics that they associated with gender roles.

Strong, aggressive, dominant, independent, coarse, loud, boastful

About 57% of 5-year-old children made stereotyped responses about gender roles by associating people in the stories with a particular sex, either male or female. For example, 5-year-old children associated being strong, aggressive, and dominant with men, while they associated being gentle and affectionate with women. Eight-year-old children had learned even more stereotypical behaviors. They associated being weak, emotional, appreciative, excitable, gentle, softhearted, meek, and submissive with women, while they associated being disorderly, cruel, coarse, adventurous, independent, ambitious, loud, and boastful with men (see photos). By the age of 11, the percentage of children who made stereotyped responses about gender roles jumped to 90%.

Differences. Researchers also found that across countries and cultures, interesting differences occurred in children's perceptions of gender roles. For example, in Germany, children associated being adventurous, confident, jolly, and steady with women, while in most other countries, these characteristics were typically associated with men.

In Japan, children associated being dominant and steady with women, while in other countries, these characteristics were typically associated with men.

Conclusions. Researchers concluded that children in 24 different countries and cultures developed knowledge of gender roles relatively early and showed remarkable similarities in choosing different gender roles and behaviors for men and women. Although there were some differences due to cultural values, there were generally more similarities in male–female gender roles across the 24 countries (J. E. Williams & Best, 1990).

Two Answers

We began with the question, Why do little boys generally grow up to be more aggressive and independent, while little girls grow up to be less aggressive and more nurturing? To this we add another question, Why do little boys and little girls from 24 different countries and cultures develop such similar male–female gender roles? There are two different but somewhat complementary answers.

The ***social role theory*** (discussed earlier—p. 395), which emphasizes social and cultural influences, states that gender differences between men and women arise from different divisions of labor.

According to social role theory, male–female gender differences developed from traditional cultural divisions of labor, in which women were childbearers and homemakers, while men were providers and protectors (Eagly et al., 2000). Because men and women performed different duties, men and women were under different social-cultural pressures to develop different gender roles. Another answer comes from a relatively new theory.

Emotional, appreciative, excitable, gentle, submissive

The ***evolutionary theory,*** which emphasizes genetic and biological forces, says that current gender differences are a continuation of the behaviors that evolved from early men and women, who adapted these different behaviors in their attempts to survive the problems of their time.

According to evolutionary theory, men increased their chances for reproduction by being dominant, controlling, and aggressive. In comparison, women increased their chances of raising their children by being concerned, sensitive, and nurturing. According to evolutionary theory, the current male–female gender differences arise from genetic and biological forces that evolved from an ancient set of mating patterns that had initially helped the species to survive (Buss, 1999; Caporael, 2001).

Because social role theory emphasizes cultural influences and evolutionary theory emphasizes genetic and biological forces, researchers suggest that by combining the two theories we can better explain the development of our current male–female gender differences (Baldwin & Baldwin, 1997).

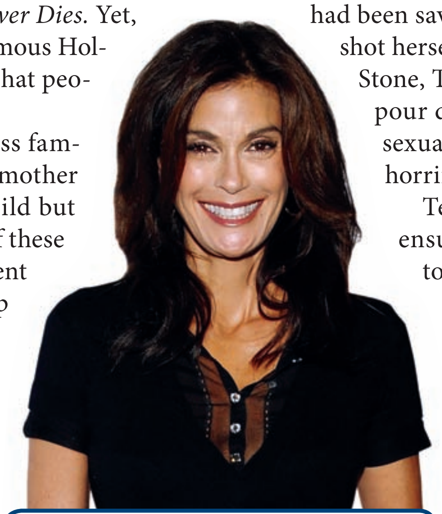
H. Application: Child Abuse

What was her terrible secret?

People probably know Teri Hatcher best for her acting roles in *Desperate Housewives, Lois & Clark: The New Adventures of Superman,* and *Tomorrow Never Dies.* Yet, even though Teri is a famous Hollywood celebrity, there is much about her life that people have only recently begun to learn.

The story. Teri was raised in a middle-class family; her father was a nuclear physicist and her mother a computer programmer. She was an only child but had relatives visit during her childhood. One of these relatives was Richard Stone, her uncle, who went out of his way to develop a close relationship with Teri. Beginning when Teri was only 5 years old, her uncle began to sexually molest her on special rides in his car. This continued for three years, after which time, Teri never saw her uncle again.

Dealing with abuse. The experience of being sexually abused was so traumatic for Teri that she never told anyone this secret. Instead, she lived every day of her life with the haunting memories of what her uncle did to her so many times. The memories were so painful and disturbing that Teri even considered taking her own life.



At 41, Teri Hatcher admitted being sexually abused by her uncle.

Confronting her fears. About 30 years after last seeing her uncle, Teri went to her parents' house to help them with a garage sale. While there, she came across a newspaper article her mother had been saving. The article was about a 14-year-old girl who shot herself and left a suicide note that implicated Richard Stone, Teri's uncle! Teri was stunned, and tears began to pour down her face. She realized that her uncle didn't sexually abuse only her, but that he had done the same horrific thing to other young girls as well.

Teri knew she had to take quick action to help ensure that her uncle would not do the same thing to anyone ever again. Concerned her uncle might escape charges of molestation, Teri gathered the courage to contact the district attorney handling his case. She then painstakingly revealed the details of her own abuse. Teri's statement helped to put Stone in prison for a 14-year sentence. The prosecutor said that without Teri's statement, the case would have been dismissed and her uncle would still be out possibly continuing to sexually abuse other young girls. After completing six years of his sentence, Stone died in prison (Associated Press, 2006c; Hatcher, 2007; Oprah, 2006).

Teri was a victim of one kind of child abuse—sexual abuse. There are several kinds of child abuse.

Kinds of Abuse

How many children are abused?

In the United States, allegations of childhood abuse and neglect are made for 5.5 million children annually (USDHHS, 2006).

Child abuse and neglect **(physical and emotional) result from inadequate care or acts of the parent that put the child in danger, cause physical harm or injury, or involve sexual molestation.**

Allegations of child abuse are made for 5.5 million children annually.

The most common kind of abuse (62%) is neglect, followed in order by physical abuse and sexual abuse (USDHHS, 2006). For example, 2-year-old Brianna was left at home alone for almost three weeks and amazingly survived by drinking water from the toilet and eating any food she could find and unwrap. When the sheriff's department found Brianna, her body was smeared with ketchup and mustard, and the sheriff stated, "Feces and urine were everywhere" (Skipp & Johnson, 2003).

The second most frequently confirmed kind of child abuse (18%) is physical abuse. For example, Karen, who was 10 years old, vividly remembered how much and how often her mother beat her. Her mother would get angry over the tiniest things, grab something handy (shoes, father's belt, potato masher), and start hitting her. One time her mother beat her so hard that Karen's legs turned black and blue. When Karen threatened to tell the police, her mother replied in an angry voice, "Go ahead. They won't believe you and they'll put you in the darkest prison" (*Time,* September 5, 1983).

The third most frequently confirmed kind of child abuse (10%) is sexual abuse. As in Teri's case, sexual abuse is most frequently committed by people who know the child, such as an acquaintance or family member, and many children are too fearful of the abuser to report their maltreatment (Douglas & Finkelhor, 2005; Finkelhor, 2002). National surveys of adults indicate that 9–32% of women and 5–10% of men have been sexually abused during their childhood; international surveys suggest similar rates of abuse (7–36% of women and 3–29% of men) (Douglas & Finkelhor, 2005; Emery & Laumann-Billings, 1998). These numbers indicate that sexual abuse, which may result in serious long-term behavioral, social, neural, and personality problems, is an international problem.

The remaining 10% of child abuse cases include emotional neglect and other kinds of abuse that do not easily fit into any category.

We'll focus on three questions related to abuse and neglect: What problems do abused children suffer? Who abuses children? How are abusive parents helped?

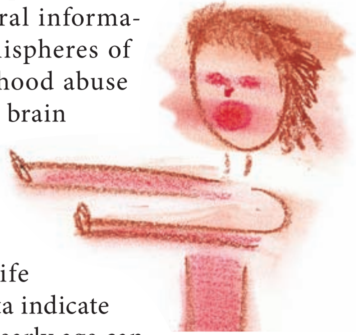
Photo Credits: top, © FilmMagic/Getty Images; bottom, © Photodisc/SuperStock

What Problems Do Abused Children Have?

Children who suffer abuse may experience a number of physical, neurological, and psychological problems. The ***physical problems*** include stomachaches, headaches, bedwetting, and abnormal hormonal changes that indicate their systems are trying to deal with large doses of stress (Yehuda, 2000).

Abused children also suffer a number of ***psychological problems,*** which include increased anxiety, social withdrawal, delays in social, cognitive, and emotional development, poor school performance, and fearful nightmares. As teenagers, abused children experience continuing problems, such as poor self-esteem, depression, loneliness, conflicts with friends, and delinquent behaviors (J. L. Davis & Petretic-Jackson, 2000). Adults who were abused as children and didn't inherit a specific form of a stress-regulating gene are more likely to display moderate to severe depression than are those who have the protective gene variation (Bradley et al., 2008).

Childhood abuse can also have enduring negative effects on a child's ***brain development and neural functioning.*** Negative effects include abnormal brain functioning, reduction in size of the brain areas that are involved in recognizing and processing emotional cues (hippocampus and amygdala), and reduction in size of the major band of fibers (corpus callosum) responsible for transferring neural information between right and left hemispheres of the brain (Teicher, 2002). Childhood abuse can also alter the functioning of a brain area responsible for releasing hormones in response to stress. Consequently, individuals who have this dysfunction experience heightened stress throughout life (McGowan et al., 2009). These data indicate that maltreatment or abuse at an early age can result in long-lasting deficits and problems in neural development and functioning.



Who Abuses Children?

Parents who abuse their children are likely to have low self-esteem and a wide range of personal problems. They are apt to be in distress, unhappy, impulsive, anxious, and aggressive and to have problems with substance abuse (Emery & Laumann-Billings, 1998; J. F. Pittman & Buckley, 2006). Recent statistics show 57.8% of people who abused children were women and 42.2% were men. Also, nearly 80% of people who abused children were parents (USDHHS, 2006).

About 30% of abused children become parents who abuse their own children, but a number of compensatory factors can prevent this from happening (J. Kaufman & Zigler, 1989). These ***compensatory factors*** include having a positive attachment to a caregiver, resolving not to repeat the abuse, having an awareness of one's early abusive experiences, having good self-esteem, and having good social support. The path from being abused to becoming an abusive parent is neither direct nor fixed and can be reversed by these compensatory factors (Glasser et al., 2001).

A child who is fussy, irritable, or sickly is more difficult to care for, especially if parents have personal problems of their own (J. R. Knutson, 1995). The interaction between a difficult child and troubled parents illustrates the principle of bidirectionality, which is one reason child abuse may occur (Maccoby, 1984).

The ***principle of bidirectionality*** says that a child's behaviors influence how his or her parents respond, and in turn the parents' behaviors influence how the child responds.

According to this principle, child abuse results from an interaction between a child's difficult traits, which tend to elicit maltreatment or abuse from the parents, and the parents' social-emotional and caregiving problems, which make it difficult for them to recognize and meet the needs of their child (J. Miller, 1995). Thus, the combination of a difficult child and parents with their own personal or drug-related problems results in a potentially explosive parent–child interaction that increases the risk for child abuse.

How Are Abusive Parents Helped?

Therapy programs that use some combination of cognitive-behavioral therapy (Module 25) and parent-training programs (Module 10) have proven relatively successful in decreasing child abuse. In general, these programs have at least two goals (L. Peterson & Brown, 1994).

1. Overcoming the parent's personal problems. Abusive parents need help in learning about and developing social relationships, which are needed for positive bonding and attachment between parent and child. Abusive parents also need training in basic caregiving skills, which involves learning how to meet the physical, social, and emotional needs of their children. Dealing with abusive parents' personal or drug problems usually requires long-term professional therapy. As parents get their personal or marital problems under control, they can concentrate on improving their interactions with their child.

2. Changing parent–child interactions. Abusive parents are less likely to use positive behaviors (smiling, praising) and are more likely to use negative behaviors (disapproving, showing anger) when dealing with their children (Reid et al., 1981). Therefore, abusive parents need to learn more positive ways of interacting. Parent-training programs, which focus on modifying ways parents interact with their children through behavior modification techniques (discussed in Module 10), are effective in helping parents increase positive interactions with their children (Timmer et al., 2005).

Clinicians and researchers recognize that, in many countries, neglect, physical abuse, and sexual abuse are serious social problems that deserve more community-based prevention methods and treatment programs than are currently available (Coates, 2006).

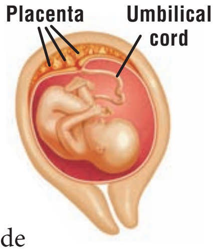
Summary Test

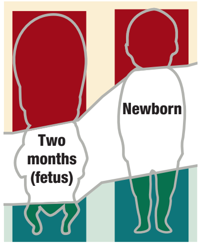
A. Prenatal Influences



1. The time from conception to birth is called the (a) ______________ period, which is divided into three parts. The two-week period that immediately follows conception is called the (b) ______________ period; it is marked by the zygote dividing into many cells. The period that includes the 2–8 weeks after conception, during which cells continue to divide and begin to differentiate into bone, muscle, and body organs, is called the (c) ______________ period. The period of development that begins two months after conception and lasts for about seven months is called the (d) ______________ period. At the end of this period, birth occurs and the fetus becomes a newborn.

2. The development of the fetus can be interrupted or damaged by a variety of toxic agents, called (a) ______________, which cause malformation of the brain or body and result in birth defects. For example, heavy drinking during pregnancy can cause a combination of physical and psychological deficits called (b) ______________, which is the leading known cause of mental retardation in the United States.

B. Newborns' Abilities



3. The newborn comes into the world with relatively well-developed sensory and perceptual responses. For example, the newborn can see, but his or her ability to see details, such as on (a) ______________, is poor. Six-month-old infants will not crawl off the visual cliff, indicating that they have developed (b) ______________ perception. Newborns have good hearing, touch, and smell and an inherited preference for sweet and salt tastes.

4. Motor development, which is the acquisition of the muscle control required for coordinated physical activity, follows two general principles. The principle that parts of the body closer to the head develop before those closer to the feet is called the (a) ______________ principle. The principle that parts closer to the center of the body develop before those farther away is called the (b) ______________ principle.

5. Development that occurs in a sequential and orderly fashion because of a genetic plan is called (a) ______________. The average age at which individuals perform various kinds of motor skills or exhibit abilities or behaviors is reflected in (b) ______________.

C. Emotional Development

6. Early and stable individual differences in attention, arousal, and reaction to new things refer to an infant's ______________, which is greatly influenced by genetic, or inherited, factors.

7. Newborns have a limited range of emotional expressions that include interest, startle, distress, disgust, and neonatal smile. During the first two years, infants develop a wide range of ______________ expressions and feelings that signal the infant's physiological needs and psychological moods.

8. The close emotional bond that develops between infant and parent (caregiver) is called (a) ______________. As the infant develops a closer attachment to her parents, she also shows more distress when her parents leave; this distress is called (b) ______________.

9. There are two kinds of attachment. Infants who use their caregiver as a safe home base from which they can wander off and explore their environments are said to be (a) ______________ attached. This kind of attachment may contribute to better emotional bonds later in life. Infants who avoid or show ambivalence toward their caregivers are said to be (b) ______________ attached. For example, these infants may cling and want to be held one minute but squirm and push away the next minute.

D. Research Focus: Temperament

10. Researchers use two different methods to study developmental processes. Repeatedly studying the same group of individuals at different ages is using the (a) ______________ method. Studying different groups of individuals who are of different ages is using the (b) ______________ method.

11. Researchers found that about one-fourth of infants show avoidance, anxiety, fear, and increased physiological arousal when in a strange or novel situation. These individuals are called shy or ______________, and the majority remain the same into adulthood. This finding supports the idea that temperaments appear early, are stable across time, and are partially under genetic control (nature).

E. Cognitive Development

12. Piaget believed that children participate in their own cognitive development by active involvement through two different processes: incorporating new information or experiences into existing knowledge is called (a) ______________; and changing one's knowledge or experiences as a result of assimilating some new information is called (b) ______________.

13. Piaget divided cognitive development into four stages. In the first, lasting from birth to about age 2, infants interact with and learn about their environments by relating their sensory experiences to their motor actions; this is called the (a) ______________ stage.

A significant development of this stage is the concept that objects or events continue to exist even if they cannot be heard, touched, or seen; this is called (b) ________________.

14. In the second stage, lasting from the age of about 2 to 7, children learn to use symbols to think about things that are not present and to help solve simple problems; this is the (a) ________________ stage. A limitation in this stage is the tendency to think of the world only from one's own viewpoint, called (b) ________________ thinking.

15. The third stage, which lasts from the age of about 7 to 11, is called the (a) ________________ stage. During this stage, children can perform a number of logical mental operations on concrete objects (ones that are physically present). The idea that the amount of a substance remains the same even in different shapes, known as (b) ________________, is mastered during the third stage.

16. During the fourth and last stage, which lasts from about age 12 through adulthood, the individual develops the ability to think about and solve abstract problems logically; this is called the (a) ________________ stage. Each of Piaget's cognitive stages is thought to be qualitatively different from the previous one because each new stage represents the development of some new (b) ________________ ability.

F. Social Development

17. How a person develops social relationships, develops a sense of self, and becomes a social being is called (a) ________________ development. Three theories of such development each emphasize a different aspect. According to Freud, a person goes through five developmental periods, called (b) ________________ stages, during which the primary goal is to satisfy innate biological needs. In contrast, Erikson divided development into eight developmental periods, in which the primary goal is to satisfy social needs; he called these (c) ________________ stages. Bandura emphasizes the importance of learning through imitation, observation, and reinforcement; this is called (d) ________________ theory.

18. Freud's five psychosexual stages are called the (a) ________________, (b) ________________, (c) ________________, (d) ________________, and (e) ________________ stages. Freud believed that the first five years leave a lasting impression on the individual's personality and social development.

19. The first five of Erikson's eight stages involve the resolution of a potential social problem between the child and his or her environment. In stage 1, the infant deals with resolving issues surrounding trust versus (a) ________________. In stage 2, the toddler must resolve issues surrounding autonomy versus shame and (b) ________________. In stage 3, the younger child deals with issues of initiative versus (c) ________________. In stage 4, the older child deals with issues that involve industry versus (d) ________________. In stage 5, the adolescent deals with issues that involve identity versus (e) ________________.

20. Early psychological difficulties increase a child's (a) ________________, which in turn increases the risk for developing later social or personality problems. However, certain emotional traits, family factors, and outside emotional support help a child overcome early problems and are said to help make the child (b) ________________ and thus develop normal social behaviors.

21. Expectations of how we should think or behave because we are male or female are called (a) ________________. One theory says that these roles develop because parents or caregivers expect, treat, and reward different kinds of behaviors depending on the child's sex; this is the (b) ________________ theory. Another theory says that children learn rules for male or female behavior through active involvement with their environments; this is the (c) ________________ theory.

G. Cultural Diversity: Gender Roles

22. Although children's perceptions of gender roles show some variation across countries and cultures, it appears that their ________________ of gender roles develops in a generally similar way at similar times.

H. Application: Child Abuse

23. Inadequate care, neglect, or acts of the parent that put the child in danger or that cause physical harm or injury or involve sexual molestation make up the definition of (a) ________________. According to the principle of (b) ________________, the child's behaviors influence how the parents respond and the parents' behaviors influence how the child responds. Two goals of treatment to stop or prevent child abuse are to help parents overcome their (c) ________________ problems and to change parent–child interactions from negative to positive.

Answers: *1. (a) prenatal, (b) germinal, (c) embryonic, (d) fetal; 2. (a) teratogens, (b) fetal alcohol syndrome (FAS); 3. (a) faces, (b) depth; 4. (a) cephalocaudal, (b) proximodistal; 5. (a) maturation, (b) developmental norms; 6. temperament; 7. emotional; 8. (a) attachment, (b) separation anxiety; 9. (a) securely, (b) insecurely; 10. (a) longitudinal, (b) cross-sectional; 11. inhibited or fearful; 12. (a) assimilation, (b) accommodation; 13. (a) sensorimotor, (b) object permanence; 14. (a) preoperational, (b) egocentric; 15. (a) concrete operations, (b) conservation; 16. (a) formal operations, (b) reasoning or thinking; 17. (a) social, (b) psychosexual, (c) psychosocial, (d) social cognitive; 18. (a) oral, (b) anal, (c) phallic, (d) latency, (e) genital; 19. (a) mistrust, (b) doubt, (c) guilt, (d) inferiority, (e) role confusion; 20. (a) vulnerability, (b) resilient; 21. (a) gender roles, (b) social role, (c) cognitive developmental; 22. knowledge; 23. (a) child abuse, (b) bidirectionality, (c) personal*

Critical Thinking

Who Matters More—Parents or Peers?

Sigmund Freud argued that parents are to blame for the problems of children. In fact, people all around the world, many psychologists included, believe parents are responsible, at least in some way, for children's problems. But, could this notion that seems like indisputable common sense be wrong?

Judith Harris, a researcher, argues that parents have minimal effect on their children's development, while peers have a much more influential role. Skeptical? Let's consider the changes in parenting styles over the years and the influence they have had on children's behavior. There has been a decrease in the use of physical punishment, yet children are no less aggressive than in previous generations. Parents shower their children with more praise and affection than ever before, yet children's self-confidence, happiness, and overall mental health are no better for it. Could it be that Harris has a valid point?

Harris states that genetics is responsible for half of children's personality and peers are essentially responsible for the other half. Therefore, Harris is not saying environment doesn't play a role in shaping a child's development, but rather that the environment that is important is the one outside of the home. She provides support for this position by presenting research on identical twins (genetically almost indistinguishable) raised together, which shows they are no more alike than identical twins reared apart. Also, how people behave at home with their parents does not predict how they behave with teachers or bosses, and how one behaves with siblings does not predict how they interact with peers. Together, these findings suggest the home environment has little effect on behavior and personality development.

Research finds that children learn how to behave appropriately by observing their peers. If they simply imitated their parents' behaviors, their behavior would be considered quite odd. Children are motivated to be similar to their peers and at the same time to be better than them. They compare themselves to their peers to understand their strengths and weaknesses. By comparing their intellectual knowledge and ability with peers, children can judge how smart they really are. After all, children don't have to know more than their parents to be considered smart; they have to know more than their peers.

Harris acknowledges how parents interact with their child affects the child's behavior at home as well as how the child will regard the parents when he or she becomes an adult. However, she states parents do not have a long-term effect on the type of person the child will become. There are many researchers who disagree with her. They cite studies showing that changes in the behavior of parents affect the behavior of children, even outside of the home. So then, which is more important to a child's development—parents or peers? It's difficult to answer with certainty. It seems both may be just as important, but perhaps in different ways. (Adapted from J. R. Harris 1998, 2006, 2007, 2009a, 2009b; Saletan, 2006)

QUESTIONS

1 If researchers wanted to observe how children typically behave with parents and with peers, what type of research setting should they use?

2 What is the name of the age-old question of which is more important—genetics or environment?

3 How would the evolutionary approach explain Harris's position that peers matter more than parents?

4 What type of learning describes the process of learning by observing peers?

5 Which level of Maslow's hierarchy of needs best matches the need for people to gain personal achievement and competency?

6 What type of parent behavior would likely have a long-term effect on children's development?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

PowerStudy 4.5™

Try out **PowerStudy's SuperModule** for Infancy and Childhood! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for Infancy and Childhood features:

- Self-paced, fully narrated learning with a multitude of animations.
- Videos on topics including prenatal health issues, development of motor skills, and perceiving gender roles.
- Interactive versions of study resources, including the Summary Test on pages 402–403 and the critical thinking questions for the article on page 404.

Suggested Answers to Critical Thinking

1. Researchers should use a naturalistic setting (p. 35), which is a relatively normal environment in which researchers gather information by observing individuals' behaviors without attempting to change or control the situation.
2. The age-old question is the nature-nurture question, which asks how much nature (genetic factors) and how much nurture (environmental factors) contributes to a person's biological, emotional, cognitive, personal, and social development.
3. The evolutionary approach would state that throughout much of human evolution, parents have had limited time for older children. So, children benefit by learning from one another. This is advantageous because if your parents raise you poorly, the larger environment, including your peers, can help compensate. Also, if your parents overly praise you and shelter you from stress, then exposure to the real social world will certainly be of benefit.
4. Learning through observation is a form of cognitive learning called observational learning (p. 224). It involves watching others perform behaviors and later performing them yourself.
5. Maslow's hierarchy of needs consists of five levels (p. 333). The fourth level is called esteem needs and best matches the need for people to gain personal achievement and competency.
6. Extreme forms of parenting would likely have lasting effects on a child's development. For instance, child abuse and neglect are associated with physical, psychological, and neurological problems.

Adolescence

Will Brandni become president?

“I will eventually become president. In 2017. I think. I’ve figured it out. I don’t want people to think, ‘She’s just a kid. She doesn’t know what’s ahead of her.’ I know the presidency will not come easy to me. I’m black, first of all, and I’m a woman. I want to be a lawyer, then work my way up in politics, become like mayor, then senator, then governor…

“Do not label me as anything. I’m an individual.”

“I know people will look into my past and say, ‘Years ago, she did this, she did that, blah, blah, blah.’ The worst thing I’ve ever done is to steal two little five-cent Bazooka gums from a 7-Eleven when I was nine. I don’t think they’ll count that against me…

“Sometimes people just expect me to make trouble because I’m ‘one of the black kids.’ Do not label me as anything. Label me as individual…

“I want everyone to know that some 12-year-olds really do think seriously about the future. I want to be a role model. I’m glad I was born black. I want to tell others, ‘Stay in there because you can do just as much good as any other person.’”

Besides talking like a philosopher, Brandni is a fun-loving adolescent who likes rap music, hanging out at the mall with her friends, and “dumb” movies. She is an above-average student, likes to write fairy tales for children, and sings in the youth choir at the neighborhood church (*Los Angeles Times,* December 22, 1991, pp. E-1, E-12).

Brandni had ambitious goals at age 12, the beginning of adolescence.

Adolescence **is a developmental period, lasting from about ages 12 to 18, during which many biological, cognitive, social, and personality traits change from childlike to adultlike.**

While it is true that adolescents, like Brandni, go through dramatic changes, experts now believe that adolescence is not necessarily marked by great psychological turmoil. Psychologists have learned that the majority of teenagers, unlike the terrible adolescents portrayed in the media, do develop a healthy sense of identity, maintain close relationships with their families, and avoid major emotional disorders (Gutgesell & Payne, 2004; Wallace, 2004). After making it through adolescence, most teenagers are ready to enter the adult world.

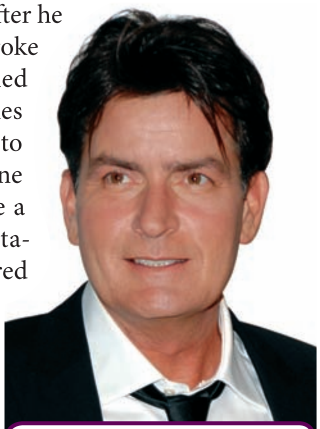
Adulthood

Did Charlie live happily ever after?

Charlie Sheen was raised among Hollywood royalty. His father is famous actor Martin Sheen, and many of his close childhood friends later became successful Hollywood actors themselves. Charlie’s background provided him with great potential to enjoy a satisfying life. But as you’ll soon learn, Charlie faced many challenges during his adulthood, only some of which he successfully overcame.

Back in high school, Charlie was best known as a star baseball player, but because of his low grades and poor classroom attendance, he was expelled shortly before his scheduled graduation. This is when Charlie decided to focus on an acting career and establishing a life for himself.

Some time later, Charlie got engaged, but after he accidentally shot his fiancée in the arm, she broke off the engagement. His personal life worsened when he became sexually involved with a series of prostitutes. Charlie then got married only to get divorced about a year later. Another decline in his personal life then occurred: this time a drug overdose followed by intensive rehabilitation. After he recovered, relapsed, and recovered again, Charlie fell in love again and married a Hollywood actress. He had two beautiful girls during this relationship, which also ended in divorce. Then Charlie fell in love again, got married, and had twin boys with his wife. Since then, however, he’s been charged with physical assault against his wife.



Charlie experienced the many ups and downs of adulthood.

Like his personal life, Charlie’s career experienced highs and lows. Early in his career he starred in two very big films, *Platoon* and *Wall Street.* His career continued to improve until his personal problems escalated. When his personal life bounced back, so did his career. It was then he was offered the opportunity to replace Michael J. Fox in *Spin City.* For his performance in this show, Charlie received a Golden Globe award. He now stars in the hit comedy series, *Two and a Half Men* (Bowles, 2009; Cruz & Chiu, 2009; NNDB, 2009).

As you can clearly see, Charlie has experienced many of the joys and pains of adulthood.

Major Periods of Change

Both Charlie and Brandni went through periods of great change. Each of us goes through three major developmental periods marked by significant physical, cognitive, personality, and social changes. We discussed childhood in Module 17. Now we’ll turn to the other two periods: adolescence and adulthood. You’ll learn how an individual’s concerns and goals undergo major changes between adolescence and adulthood.

What’s Coming

We’ll explain the personality, social, cognitive, and physical changes that individuals undergo from adolescence through adulthood and discuss some of the challenges and problems that adolescents and adults face during each of these periods.

We’ll begin with perhaps the biggest change in adolescence—puberty.

Photo Credits: left, *Los Angeles Times,* Photo by Tammy Lechner; right, © FilmMagic/Getty Images

A. Puberty & Sexual Behavior

Why is puberty such a big deal?

A teenager leaves behind the mind and body of a child and begins to take on the mind and body of an adult. This great change from child to adult is full of challenge, excitement, and anxiety for the adolescent and the parents. Perhaps the biggest event in changing from a child to an adult is the onset of puberty, which is altogether interesting, wondrous, and potentially very stressful.

Puberty **refers to a developmental period, between the ages of 9 and 17, when the individual experiences significant biological changes that result in developing secondary sexual characteristics and reaching sexual maturity.**

As puberty triggers dramatic changes in the structure and function of our bodies, we simultaneously experience dramatic changes in our thoughts, personalities, and social behaviors. To understand why puberty changed our minds, we must first learn how puberty changed our bodies.

Girls during Puberty

Every girl wants to grow up so she can finally be a woman. Becoming a woman means going through puberty and experiencing three major biological changes that occur between ages 9 and 13. The onset of puberty usually occurs about two years earlier in girls (average of 10.5 years) than in boys (average of 12.5 years).

1 Puberty sets off a surge in ***physical growth,*** which is marked by an increase in height that starts on average at 9.6 years. This growth spurt begins about 6–12 months before the onset of breast development.

2 Puberty triggers a physiological process that results in a girl's reaching ***female sexual maturity,*** which primarily involves the onset of menarche.

Menarche **is the first menstrual period; it is a signal that ovulation may have occurred and that the girl may have the potential to conceive and bear a child.**

In the United States, menarche occurs on average at 12.5 years, about 2.5 years after the beginning of breast development. For reasons of diet, exercise, and genes, age of menarche varies with society and country (S. E. Anderson et al., 2003; Chumlea et al., 2003; Ellison, 2002).

The onset of menarche is triggered by an area of the brain called the ***hypothalamus,*** which releases a hormone called ***kisspeptin*** that helps to stimulate the ***pituitary gland*** to produce hormones. These hormones travel throughout the bloodstream and stimulate the ovaries to greatly increase production of female hormones (Kotulak, 2006; McKie, 2005; Messager, 2006).

Estrogen **is one of the major female hormones. At puberty, estrogen levels increase eightfold, which stimulates the development of both primary and secondary sexual characteristics.**

3 Puberty marks a major change in the girl's body as she develops female secondary sexual characteristics.

Female secondary sexual characteristics, **whose development is triggered by the increased secretion of estrogen, include growth of pubic hair, development of breasts, and widening of hips.**

In girls, the onset of secondary sexual characteristics begins at 10.5 years (the range is from age 9 to age 18) and continues for about 4.5 years.

Early versus late maturing. Girls who are early maturing—that is, who go through puberty early—may encounter psychological problems because they have not yet acquired the adult personality traits and social skills that are needed for normal and healthy functioning in their newly developed adult bodies (Dorn et al., 2003).

Boys during Puberty

Every boy wants to grow up so he can finally be a man. Becoming a man means going through puberty and experiencing three major biological changes that occur between ages 10 and 14. The onset of puberty in a boy usually occurs about two years later than in a girl.

1 Puberty triggers an increase in ***physical growth,*** especially height, generally at 13–14 years of age. The increase in height may be dramatic, and a boy may feel strange as he discovers that he is taller than his mother and as tall as or taller than his father.

2 Puberty starts a physiological process that results in a boy's reaching ***male sexual maturity,*** which includes growth of the genital organs—testes and penis—and production of sperm. The onset of genital growth begins at around 11.5 years (the range is from age 9 to age 16) and continues for approximately three years. The production and release of sperm begin at 12–14 years of age.

The increase in genital growth and the production of sperm are triggered by the ***hypothalamus,*** which stimulates the male pituitary gland. The pituitary in turn triggers the testes to increase production of testosterone by as much as 18 times more than before puberty.

Testosterone, **which is the major male hormone, stimulates the growth of genital organs and the development of secondary sexual characteristics.**

3 The increased production of testosterone triggers the development of male secondary sexual characteristics.

Male secondary sexual characteristics, **which are triggered by the increased secretion of testosterone, include the growth of pubic and facial hair, development of muscles, and a change (deepening) in voice.**

These changes usually occur between 12 and 16 years of age, but there is a wide range in their development.

Early versus late maturing. Generally, boys who are early maturing, which means they go through puberty earlier, are found to be more confident, relaxed, socially responsible, popular, and highly regarded by their peers. In comparison, boys who go through puberty later (are late maturing) are found lacking in self-confidence and self-esteem, more dependent on their parents, and less highly regarded by peers.

However, many of the psychological differences between early- and late-maturing girls and boys decrease and disappear with age (Sigelman & Rider, 2009). One interesting difference between boys and girls during puberty is that generally boys see themselves as being physically attractive, while many girls doubt their attractiveness and are constantly comparing themselves with other girls (Rodriguez-Tome et al., 1993).

During puberty, boys and girls become physically sexually mature, a brand-new body state that raises many difficult questions for adolescents.

Adolescents: Sexually Mature

Now what do I do?

In the United States, about 30 million youths between the ages of 10 and 17 are looking for answers to a very important and burning question: Now that I am sexually mature, what do I do? Part of the difficulty that adolescents have in making decisions about how to behave sexually is that they receive conflicting answers.

Conflicting Answers

On the one hand, the media (movies, television, magazines), as well as peers, friends, and classmates, often discuss or portray sex in exciting ways that stimulate and encourage adolescents to try sex, often before they are emotionally ready (L. Ali & Scelfo, 2002). For example, in a study of 174 girls, most said that they had been too young (average age was 13) at the time of their first intercourse. The reasons (in order of frequency) that they gave for engaging in sex were that they were physically attracted or curious, were alone with their partner, and knew that all their friends were having sex. Looking back, most of these girls wished they had waited longer before having sexual intercourse because they had not been ready and had not appreciated the risks of pregnancy and disease (S. L. Rosenthal et al., 1997).

Advice. On the other hand, most parents, mental health organizations, and religious groups advise adolescents not to engage in sex too early and to wait until they are more emotionally mature and involved in an intimate relationship (Rabasca, 1999). Researchers advise more parent–teen discussions of sexual behavior because one study found that 50% of mothers whose 14-year-olds were sexually active mistakenly believed that their teens were still virgins (R. Blum, 2002). In addition, teens often lack basic information about potential problems, as indicated by 30% of teens who had oral sex but were unaware that this activity could result in sexually transmitted diseases (J. Davis, 2003).

Approach. Trying to explain sexual development in teenagers and the complicated relationship between sex and love has given rise to the BioPsychoSocial model.

Sexual activity of teenage boys and girls is about equal.

Photo Credit: center, © Ted Horowitz/Alamy

The ***BioPsychoSocial approach*** views adolescent development as a process that occurs simultaneously on many levels and includes hormonal, neural, sexual, cognitive, social, cultural, and personality changes that interact and influence each other (Herdt, 2004; D. L. Tolman et al., 2003).

According to the BioPsychoSocial approach, sexual behavior cannot be discussed independently of hormonal, cognitive, personality, and emotional factors. For example, sex hormones trigger important physical changes but also influence mood and behavioral changes, such as perceiving peers as romantically attractive (J. Schwab et al., 2001). Finding someone romantically attractive naturally leads to seeking a more intimate relationship, which raises the question of becoming sexually active.

Decisions about Becoming Sexually Active

In the early 1990s, nearly 60% of high-school students reported engaging in sexual intercourse, but by 2005, the percentage had dropped 10%, to fewer than half of respondents (CDC, 2008b). In the 1990s, teenage boys reported earlier and more sexual activity than teenage girls, but by the early 2000s, gender differences no longer existed (CDC, 2004; B. E. Wells & Twenge, 2005).

Between the late 1980s and early 2000s, the number of teenagers who reported NOT having sexual intercourse rose about 10% (CDC, 2004). The reasons teenagers gave for abstaining from sexual activity included having caring parents, feeling unready, wanting to have some control over their futures, participating in abstinence programs, and having concerns about sexually transmitted diseases. As one teenager said, "Just look at everything—TV, movies. The culture today makes it seem OK to have sex whenever, however or with whoever you want. I just disagree with that" (L. Ali & Scelfo, 2002, p. 63). In fact, research demonstrates that watching more sexy TV shows is related to beginning sexual intercourse earlier (RAND, 2008). Besides media influences, many teenagers report they constantly have to deal with peer pressures to be sexually active or else be considered strange. Teenagers who do become sexually active face a number of potential problems.

Problems. One problem is that the age at which teenagers engage in sexual activity is earlier than what they think is the best age. Although the median age for first intercourse was 17.4 years for girls, about half the girls (48%) said the best age for first intercourse is between 18 and 20 years old. Teenage girls report that sex and pregnancy are the number one issues they face today. However, curiosity, media, and peer pressure play a large role in motivating sexual activity (L. Ali & Scelfo, 2002). Although puberty prepares teenage bodies for engaging in sexual behavior, the majority of teenagers (especially girls) report not being emotionally, psychologically, or mentally prepared to deal with strong sexual desires and feelings.

Another problem is only 31% of boys and 21% of girls who become sexually active report using contraceptives every time they have intercourse (CDC, 2004). This can lead to two major problems: the spread of sexually transmitted diseases (STDs), including AIDS, and unwanted pregnancies. The risk of STDs is especially high, as teens account for half of the 19 million new cases each year (B. Healy, 2008).

It's important to point out that engaging early in sexual intercourse does not inevitably lead to problems. In fact, a recent research study found that teens who had sex earlier had less delinquency and antisocial behavior years later, rather than more (Harden et al., 2008).

We'll next examine a number of mental and psychological changes that accompany the teenage years.

B. Cognitive & Emotional Changes

Definition

Why is Branndi's head spinning?

When most adults and especially current parents of teenagers hear the word *adolescence,* they often get a pained look as they remember a time full of problems. Until the early 1990s, researchers believed that adolescence was primarily a time of storm and stress, of intense feelings, huge mood swings, and irritating parental conflicts. However, current research paints a different picture of adolescence. Yes, storm and stress and intense mood swings and parental conflicts are likely to occur during adolescence, but they come and go, and not all adolescents have a terrible time (Arnett, 2000a). Research also finds that along with the storm and stress, adolescence is a time for tremendous growth in emotional, social, and cognitive development as teenagers go from childhood to adulthood (Lerner & Galambos, 1998).

"I believe God lets awful things happen to teach us a lesson."

We have already discussed the dramatic physical changes and sexual feelings that occur during puberty and the problems adolescents have in deciding what to do with their newly developed sexual maturity. Along with sexual maturity, adolescents develop new ways of thinking and reasoning, which represents a major change in cognitive development.

Cognitive development **refers to how a person perceives, thinks, and gains an understanding of his or her world through the interaction and influence of genetic and learned factors.**

For example, at the beginning of this module we told you that, during adolescence, Branndi (left photo) would undergo major changes in reasoning and thinking. For example, here are some of her thoughts about the condition of the world:

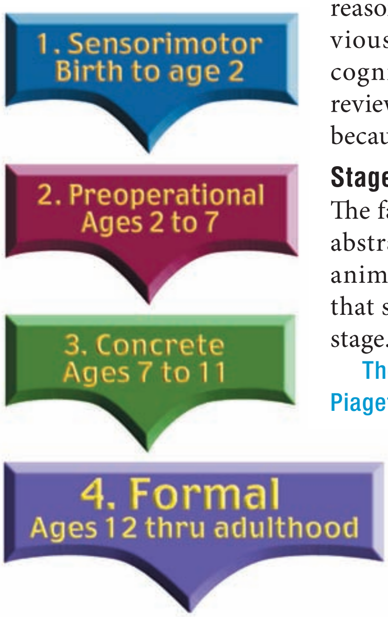
> "I don't believe in the Pledge of Allegiance. I don't say it, because they're telling a lie—'liberty and justice for all.' . . . My first step into politics will be mayor. I write lots of letters to Tom Bradley [former mayor of Los Angeles] about things like animal rights. But he just sent me, you know, one of those typed things. I don't think it's right . . . I'm very outspoken. I worry about things—sex, rape, and stuff like that . . . I believe in God. I believe God lets awful things happen to teach us a lesson . . ." (*Los Angeles Times,* December 22, 1991, p. E-13).

There's no question that 12-year-old Branndi is full of abstract thinking, is very outspoken, and holds absolute opinions on a variety of concrete and abstract issues. Her views illustrate one of the most significant changes in cognitive development during adolescence, which is the ability to think about abstract issues, such as the meaning of liberty, justice, and God. This kind of abstract thinking indicates that Branndi is entering Piaget's fourth cognitive stage, called formal operations, which marks the beginning of thinking and reasoning like an adult.

Piaget's Cognitive Stages: Continued

What's new about a teenager's thinking?

As you may remember from Module 17, Piaget's theory of cognitive development is that we all go through four distinct ***cognitive stages*** (left figure). As we go through each cognitive stage, we acquire a new and distinct kind of reasoning and thinking that is different from and more advanced than the reasoning abilities we possessed at our previous stage. We discussed Piaget's four cognitive stages in Module 17, but we'll review stage 4, the formal operations stage, because it begins in adolescence.



Stage 4: Formal Operations

The fact that 12-year-old Branndi is using abstract concepts, such as liberty, justice, animal rights, and God, is good evidence that she is entering the formal operations stage.

The *formal operations stage,* the last of Piaget's four cognitive stages, extends from about age 12 through adulthood. During this stage, adolescents and adults develop the abilities to think about abstract or hypothetical concepts, to consider an issue from another's viewpoint, and to solve cognitive problems in a logical way.

Having the ability to think about and discuss abstract concepts means that adolescents can critically consider their beliefs, attitudes, values, and goals as well as discuss a wide range of topics important to their becoming adults. For instance, when adolescents were asked about their major concerns, tops on their lists were getting married, having friends, getting a good job, and doing well in school. Each of these concerns involves the ability to discuss abstract concepts, which is a cognitive skill that they are learning at the formal operations stage.

"My major concerns are doing well in school and having friends."

One of the interesting questions about adolescents is why some seem so slow to develop thinking and reasoning skills that prepare them to deal with typical problems and stressful situations that occur during adolescence. For example, many adolescents report that they were not prepared to have sex but it just happened, or they fight continually with their parents, or they do stupid things like drink and then drive. Researchers have only recently discovered that the answer involves the developing adolescent's brain.

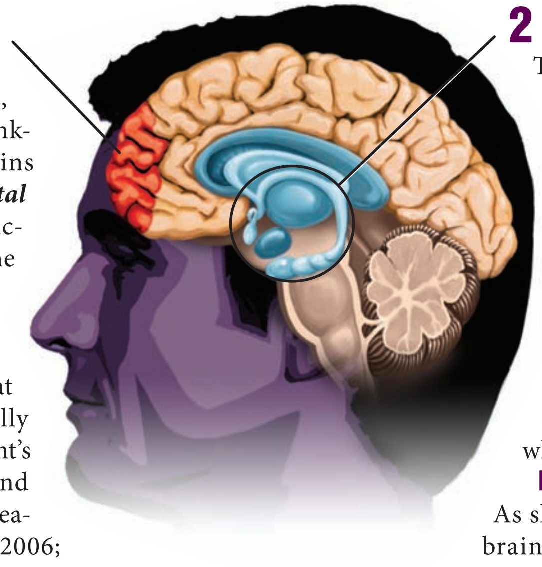
Brain Development: Reason and Emotion

A difficult problem for parents is dealing with seemingly irresponsible or impulsive bad behaviors or decisions of their teenagers. Parents believe their teens should know better, and until recently, researchers thought that teens should know better because they believed that teenage brains were fully developed by puberty. However, new findings indicate that teenage brains are still developing, especially areas involved in clear thinking and reasoning (Crews, 2006).

PowerStudy 4.5™

Module 4

B. Studying the Living Brain
D. Control Centers: Four Lobes
E. Limbic System: Old Brain

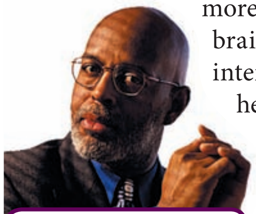


1 Prefrontal cortex: executive functions

Every company has an executive officer who is responsible for making decisions, day-to-day planning, organizing, and thinking about the future. Similarly, our brains have an executive area, called the ***prefrontal cortex,*** which is involved in similar functions and is located near the front of the brain (p. 75) (right figure).

Researchers used brain scans (p. 70) to take pictures of the neural development of teenage brains. Unlike previous beliefs that an adolescent's prefrontal cortex was fully developed, researchers found the adolescent's prefrontal cortex was still developing and thus did not yet have the ability to think, reason, decide, or plan like an adult (Luna, 2006; Shute, 2009).

Vulnerability. Beginning at about age 11 and continuing into young adulthood, the brain undergoes major "rewiring" and reorganization and is especially vulnerable to traumatic adolescent experiences, such as being physically or sexually abused or bullied, feeling depressed, and abusing drugs. Research suggests that alcohol causes more injury to teenage brains than it does to adult brains. These kinds of traumatic experiences can interfere with the adolescent's brain developing a healthy and reasonable executive center (Crews, 2006; Shute, 2009).



"As executive officer, I'm responsible for thinking, planning, and making decisions."

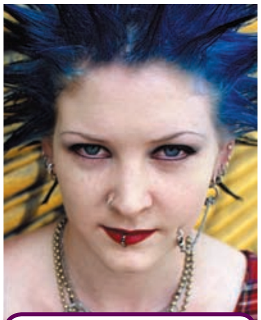
Risk-taking behavior. The finding that executive functions in the adolescent's brain are not yet fully developed helps explain many of the adolescent's seemingly irresponsible behaviors. For example, adolescents have about twice the rate of adults in transmitting venereal diseases because only 50% think to use condoms, and they have 20 times the rate of automobile accidents as adults because adolescents don't worry about drinking, driving, and speeding (C. E. Irwin et al., 2002). The previous explanation for why adolescents engaged in risk-taking behavior was they felt invulnerable and had no fear of injury. Researchers now explain adolescents' tendency to take risks is due to the executive manager of their behaviors, their prefrontal cortex, being underdeveloped, which means they don't have the neural bases to analyze risks and make intelligent decisions (Luna, 2006). One researcher described the teenage brain very well by saying it "is like a car with a good accelerator but a weak brake" (L. Steinberg, 2007). We'll discuss how this brain research applies to teen driving in the Critical Thinking section (p. 430).

Another reason adolescents have a tendency to engage in risk-taking behaviors involves a different part of their brain that's involved in emotional behaviors.

2 Limbic system: emotional behaviors

Teenagers are known to act impulsively, such as getting a tongue pierced on a dare, and experience wide mood swings. As one parent said, "It's hot and cold, nasty and nice. One minute loving me, one minute hating me." What parents don't realize is a teenager's prefrontal cortex, which acts like an executive officer, is not fully developed, so an adolescent has less control over his or her emotional and impulsive behaviors. This explains why teens are so easily upset when parents can't understand why (Shute, 2009).

Moody, emotional, and impulsive behaviors. As shown in the left figure, in the center of the brain is a circle of structures that make up our emotional brain, called the limbic system (p. 80). The ***limbic system*** is involved in a wide range of emotional behaviors, such being ecstatic over getting a date, feeling depressed when failing a test, and getting angry when insulted. Research found that sex hormones (testosterone in males and estrogen in females), which are secreted in abundance during puberty, increase the growth of limbic system structures (amygdala, hippocampus). Researchers believe the increased size and function of the limbic system account for a teenager's irritability and increase in talking aggressively with others, such as their parents (Whittle et al., 2008).



"I was dared to get my lip and nose pierced."

Conclusion. Researchers are finding that the adolescent's brain has an underdeveloped prefrontal cortex, or executive officer, but a well-developed limbic system, or emotional center (L. Steinberg, 2004). This combination of a weak executive officer and a strong emotional center results in many of the unthinking and irritating behaviors of adolescents, such as taking risks, switching moods, and acting impulsively. As one researcher summarized, "Good judgment is learned but you can't learn it if you don't have the necessary hardware (neural development)" (Yurgelun-Todd, 1999, p. 48).

An adolescent's lack of a strong executive officer (prefrontal cortex) will also affect moral judgment, which is our next topic.

"One minute I'm laughing and the next I'm crying."

B. Cognitive & Emotional Changes

Kohlberg's Theory of Moral Reasoning

Would you steal to save a friend?

Suppose your best friend is dying of cancer. You hear of a chemist who has just discovered a new wonder drug that could save her life. The chemist is selling the drug for $5,000, many times more than it cost him to make. You try to borrow the full amount but can get only $2,500. You ask the chemist to sell you the drug for $2,500 and he refuses. Later that night, you break into the chemist's laboratory and steal the drug. Should you have done that?

Did you decide that it would be all right to steal the drug to save the life of your dying friend? If you did, how did you justify your moral decision? Lawrence Kohlberg (1984) and associates presented similar dilemmas to individuals who were asked to explain their moral decisions. On the basis of such studies, Kohlberg explained the development of moral reasoning in terms of three levels.

Three Levels of Moral Reasoning

Level 1 Self-Interest

The ***preconventional level,*** which represents Kohlberg's lowest level of moral reasoning, has two stages. At stage 1, moral decisions are based primarily on fear of punishment or the need to be obedient; at stage 2, moral reasoning is guided most by satisfying one's self-interest, which may involve making bargains.

For example, individuals at stage 1 might say that you should not steal the drug because you'll be caught and go to jail. Individuals at stage 2 might say that you can steal the drug and save your best friend, but in return you'll have to give up some freedom by going to jail. Most children are at the preconventional level.

Level 2 Social Approval

The ***conventional level,*** which represents an intermediate level of moral reasoning, also has two stages. At stage 3, moral decisions are guided most by conforming to the standards of others we value; at stage 4, moral reasoning is determined most by conforming to laws of society.

Individuals at stage 3 might say that you should steal the drug since that is what your family would expect you to do. Individuals at stage 4 might say that you should not steal the drug because of what would happen to society if everybody took what they needed. Many adolescents and adults are at this level.

Level 3 Abstract Ideas

The ***postconventional level,*** which represents the highest level of moral reasoning, has one stage. At stage 5, moral decisions are made after carefully thinking about all the alternatives and striking a balance between human rights and laws of society.

Individuals at stage 5 might say that one should steal the drug because life is more important than money. (Stage 6, which appeared in earlier versions of Kohlberg's theory, has been omitted in later versions because too few people had reached it.) Some, but not all, adults reach the postconventional level.

Kohlberg's theory has two distinct features. First, he classifies moral reasoning into three distinct levels—preconventional, conventional, and postconventional. Second, he suggests that everyone progresses through the levels in order, from lowest to highest. However, not everyone reaches the higher stages of moral development.

Next, we'll evaluate Kohlberg's theory and its present status.

Evaluating Kohlberg's Theory

Stages. Kohlberg hypothesized that everyone goes through the five stages in sequence, with no skipping of stages. Researchers reviewed 45 Kohlberg-type studies conducted in 27 cultures and concluded that, as Kohlberg assumed, we go through the stages in order but not everyone reaches the higher stages (Damon, 1999; Helwig, 1997).

Thinking versus behaving. Kohlberg's stages present different kinds of moral thinking that may or may not predict how someone behaves. Thus, Kohlberg focused on the development of moral thinking, not on the development of moral behavior in real-life situations (Damon, 1999).

Carol Gilligan (1982) criticized Kolhberg's stages by saying that, in making moral decisions, women use more of a ***care orientation,*** which is based on caring, having concern for others, and avoiding hurt, while men use more of a ***justice orientation,*** based on law, equality, and individual rights. However, research shows both men and women use a mixture of care and justice orientations, depending on the situation (Jaffee & Hyde, 2000).

Brain or neural factors. Kohlberg constructed his theory before researchers were able to study the structures and functions of the living brain (pp. 70–71). We have explained that the teenage brain has an underdeveloped prefrontal cortex, which results in an underdeveloped executive area and limits a teenager's ability to think, reason, and make intelligent decisions needed for moral reasoning (Luna, 2006). Also supporting the role of the prefrontal cortex in moral reasoning are findings that individuals who had their prefrontal cortex damaged in infancy had difficulty learning the normal social and moral rules in childhood and adolescence (A. Damasio, 1999). More recently, researchers identified different brain areas involved in moral decisions: Making ***impersonal moral decisions,*** such as keeping the money found in a stranger's wallet, involved areas associated with retrieving information (p. 242); in comparison, making ***personal moral decisions,*** such as keeping the money found in a fellow worker's wallet, involved areas associated with emotions. Thus, when we make moral decisions, especially those involving personal concerns (abortion, death penalty), we use not only reasoning and logic but also our gut feelings or emotions (J. D. Greene et al., 2004). Making moral decisions appears to involve some kind of unconscious process (Hauser, 2007). We may not be aware that our gut feelings are directing our moral decisions.

Researchers are now studying other aspects of moral judgment and development, such as prosocial behavior (helping others), moral emotions (remorse, guilt), and empathy (Killen & Smetana, 2006).

Moral reasoning and cognitive development are also influenced by the kinds of rules that parents use, which is our next topic.

Parenting Styles and Effects

Were your parents easy or strict?

During adolescence, teenagers experience several major changes in cognitive and emotional development. These changes are influenced by both biological factors, such as brain development, and environmental factors, such as the influence of peers and parents. For instance, if someone asked how your parents raised you, would you answer that they were strict, supportive, easy, or hard? It turns out that parents' rules, standards, and codes of conduct influence how a teenager develops a sense of independence and achievement (Baumrind, 1991). We'll discuss how parental rules can affect the cognitive and emotional development of teenagers.

Personal Experiences

When teenagers were asked how they responded to their parents' rules, here's what Ida and Chris replied (photos below).

Ida, age 17. "I live in a strict Italian home. Sometimes my parents are really, really great, but their rules for me are absolutely ridiculous. So I get around them. My friends will tell you I'm a good kid. I don't drink. I don't do drugs. I don't smoke. But my parents think that, if I've gone out on a Friday night and I ask to go out Saturday, too, I'm asking for the world . . . So I lie a lot . . . A lot of people know I do this, but nobody yells at me for it, because I'm a good kid, and my parents' rules are so ridiculous."

Chris, age 18. "My parents never make their punishments stick. Like, I'll get my Jeep taken away for a week, and I'll get it back within six hours. Why? Because my parents hate to see their kids unhappy, and I know it, so I play right into it. They'll punish me by not letting me go out, so I'll walk around the house, slam the door occasionally, this, that . . . and after awhile this just plays on them, and they feel bad, and they let me out" (*Parade* magazine, July 14, 1991, pp. 6–7. Reprinted with permission from *Parade*. Copyright © 1991).

Ida says, "I had to get around my parents' strict rules."

Chris says, "I acted unhappy so my parents gave in."

After reading these two descriptions, you can see that Ida's parents are the opposite of Chris's. How do such different styles of parenting affect adolescents' development? To answer this question, psychologist Diana Baumrind (1991, 1993) carried out a series of longitudinal studies on parent–child and parent–adolescent interactions. She has identified a number of parenting styles that are associated with different kinds of adolescent development.

Different Styles of Parenting

We'll focus on three of Baumrind's parenting styles: authoritarian parents, authoritative parents, and permissive parents.

Authoritarian parents **attempt to shape, control, and evaluate the behavior and attitudes of their children in accordance with a set standard of conduct, usually an absolute standard that comes from religious or respected authorities.**

For these parents, obedience is a virtue, and they punish and use harsh discipline to keep the adolescent in line with their rules. This parenting style seems to describe Ida's parents. Boys from authoritarian families are found to be relatively hostile, while girls are found to be relatively dependent and submissive. This description fits Ida, who admits to problems with being independent.

Authoritative parents **attempt to direct their children's activities in a rational and intelligent way. They are supportive, loving, and committed, encourage verbal give-and-take, and discuss their rules and policies with their children.**

Authoritative parents value being expressive and independent but are also demanding. The children of such parents tend to be competent. In addition, girls are achievement-oriented and boys are friendly and cooperative.

Permissive parents **are less controlling and behave with a nonpunishing and accepting attitude toward their children's impulses, desires, and actions; they consult with their children about policy decisions, make few demands, and tend to use reason rather than direct power.**

This parenting style seems to describe Chris's parents. Girls with such parents are less socially assertive, and both boys and girls are less achievement-oriented.

Effects of Parenting Styles

Each of the three parenting styles has different costs and benefits. Authoritarian parents, who are very demanding, benefit by preventing adolescent behavioral problems but at some cost to adolescents, who tend to be more conforming and have lower self-esteem. Authoritative parents, who state their values clearly, benefit by having loving and supportive parent–teenager interactions, which further benefit their teenagers, who tend to be more friendly, cooperative, and achievement-oriented (Hickman et al., 2000; Vazsonyi et al., 2003). Permissive parents benefit by having to make fewer demands and enforcing fewer rules but at some cost to adolescents, who may be less socially assertive and less achievement-oriented than adolescents with authoritative parents (Baumrind, 1991, 1993). Thus, different parenting styles can have significantly different effects on the cognitive, social, and personality development of adolescents.

Which is better, being too easy or too strict?

Even though parenting styles influence adolescent development, new research finds that siblings may have the strongest influence on who we become in the long term. This isn't too surprising, as we spend every day of our childhood with our siblings and they remain in our lives long after our parents leave us. Through all of the sibling conflict, we learn how to negotiate, compromise, and maintain lasting relationships, which can help us to have successful adult relationships, such as those with our spouse/partner and colleagues (Kluger, 2006b).

B. Cognitive & Emotional Changes

Adolescence: Big Picture

What are the major changes?

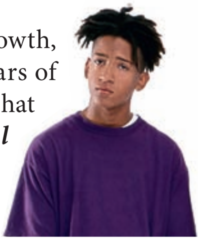
There are 30 million of us.

In the United States, there are about 30 million youths (ages 10 to 17) who are currently going through adolescence, a period of considerable physical, neurological (brain), cognitive, and emotional change. Although adolescence is a time of some storm and stress, it is also a time for tremendous personal growth. We'll review some of the major changes that occur during adolescence.

1 Girls during Puberty

Puberty sets off a surge in physical growth, which is marked by an increase in height that starts on average at 9.6 years. Puberty triggers a physiological process that results in a girl's reaching ***female sexual maturity,*** which involves primarily the onset of ***menarche,*** or the first menstrual period, at an average age of 12.5 years. The onset of menarche is triggered by the ***hypothalamus,*** which releases a hormone called ***kisspeptin*** that helps to stimulate the ***pituitary gland*** to produce hormones (Kotulak, 2006). These hormones stimulate the ovaries to produce female hormones including ***estrogen,*** which stimulates the development of both primary and secondary sexual characteristics, such as development of pubic hair and breasts.

2 Boys during Puberty



Puberty triggers an increase in physical growth, especially height, generally at 13 or 14 years of age. Puberty starts a physiological process that results in a boy's reaching ***male sexual maturity,*** which includes growth of the genital organs—testes and penis—and production of sperm at 12–14 years of age. The increase in genital growth and the production of sperm are triggered by the ***hypothalamus,*** which stimulates the male pituitary gland. The pituitary in turn triggers the testes to increase production of ***testosterone,*** which is the major male hormone and stimulates the growth of genital organs and the development of secondary sexual characteristics, such as growth of pubic and facial hair, development of muscles, and a change (deepening) in voice.

3 Sexual Maturity

In the early 1990s, nearly 60% of high-school students reported engaging in sexual intercourse, but by 2005, the percentage had dropped 10%, to fewer than half of respondents (CDC, 2008). In the 1990s, teenage boys reported earlier and more sexual activity than teenage girls, but by the early 2000s, gender differences no longer existed (CDC, 2004; B. E. Wells & Twenge, 2005). Between the late 1980s and early 2000s, the number of teenagers who reported NOT having sexual intercourse rose about 10% (CDC, 2004).

4 Piaget's Stages Continued

1. Sensorimotor
2. Preoperational
3. Concrete
4. Formal

According to Piaget's theory, children pass through four different cognitive stages—(1) sensorimotor, (2) preoperational, (3) concrete operations, and (4) formal operations—in that order but at individual rates. With each stage, the child adds a new and qualitatively different kind of thinking or reasoning skill that helps the child make better sense of the world. Adolescents are entering Piaget's fourth stage, called the formal operations stage, which begins at about age 12 and extends through adulthood. During this stage, adolescents develop the abilities to think about abstract or hypothetical concepts, to consider an issue from another's viewpoint, and to solve cognitive problems in a logical way. These cognitive abilities are very useful during adulthood.

5 Brain Development: Reason & Emotion

Researchers are finding that the adolescent's brain has an underdeveloped prefrontal cortex or executive officer but a well-developed limbic system or emotional center (L. Steinberg, 2004). This combination of a weak executive officer and a strong emotional center results in many of the unthinking, irresponsible, and irritating behaviors of adolescents. For example, the lack of a strong executive officer (prefrontal cortex) explains why adolescents engage in risky behaviors, switch moods suddenly, and act impulsively. As one researcher summarized, "Good judgment is learned but you can't learn it if you don't have the necessary hardware (neural development)" (Yurgelun-Todd, 1999, p. 48).

6 Kohlberg's Theory of Moral Reasoning

Kohlberg hypothesized that everyone goes through three levels of moral reasoning. Level 1, the preconventional level, involves stage 1 (fear of punishment) and stage 2 (self-interest). Level 2, the conventional level, involves stage 3 (conforming to the standards of others) and stage 4 (conforming to the standards of society). Level 3, the postconventional level, has only stage 5 (balancing human rights and society's laws). There is support for Kohlberg's assumption that individuals progress through the stages in order and that not everyone reaches the higher stages (Damon, 1999). Since Kohlberg's time, researchers have found several brain or neural factors (prefrontal cortex, emotional areas) that play a role in making moral decisions.

We'll discuss some of the cognitive changes that make people realize that they're not kids anymore.

PowerStudy 4.5™

Module 4

B. Studying the Living Brain

Beyond Adolescence

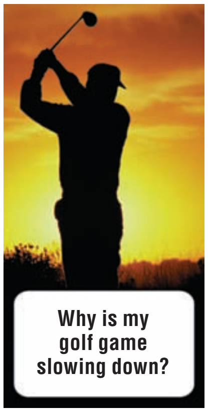
In your 20s and 30s, cognitive abilities are usually at their peak.

In your 40s and 50s, memory problems usually begin and continue.

In your 60s, 70s, and 80s, there's slowing in cognitive processes.

As teenagers enter their 20s, they face a number of major changes, such as deciding about going to college, leaving home for perhaps the first time, choosing a career or major, entering the job market, and searching for a serious relationship (Arnett, 2000b). The 20s are a time when executive abilities (thinking, planning, deciding, remembering) are sharp, partly because the brain's prefrontal cortex is now more fully developed. Cognitive or executive abilities usually remain sharp through the 30s. But beginning in the 40s and continuing through the 50s and 60s, there is a gradual decline in some cognitive abilities, especially in the ability to remember things. We'll discuss some changes in cognitive abilities as we age.

Changes in Cognitive Speed



Why is my golf game slowing down?

From about ages 20 to 40, cognitive skills remain relatively stable. However, between 40 and 80, there is a general slowing of some cognitive processes. Beginning in the late 50s, there is a slowing of three cognitive processes:

1 There is a slowing in ***processing speed,*** which is the rate at which we encode information into long-term memory or recall or retrieve information from long-term memory.

2 There is a slowing in ***perceptual speed,*** which is the rate at which we can identify a particular sensory stimulus.

3 There is a slowing in ***reaction time,*** which is the rate at which we respond (see, hear, move) to some stimulus.

This slowing in processing, perceiving, and reacting partly explains why older people react more slowly when driving a car or playing golf and are slower to make decisions or understand and follow instructions. For example, partly because of the slowdown in these processes, there is a professional golf tour for seniors only (over age 50); they can no longer keep up with younger golfers.

Besides a slowing in cognitive speed, older adults experience a problem in remembering things.

Changes in Memory

Beginning in the 40s and continuing into old age, most people complain about not remembering things. Researchers concluded older adults have no trouble remembering the big picture (name of a movie) but do forget many of the small details (who played the starring role). In comparison, young adults easily remember the big picture plus all the details (Schacter, 2001). So as people move into their 50s, 60s, and 70s, their complaints are true: They forget details (names, places, groceries) that may be bothersome but are usually unimportant.

Am I losing my memory?

Memory differences. Young adults in their 20s excel at encoding (storing) and recalling vast amounts of detail but are not as good at making sense of what all the details mean. In comparison, mature adults in their 50s excel at making sense of information but forget many details.

Brain changes. Decreases in memory skills result from the slowing down of memory abilities, reasoning processes, and focusing of attention. Brain scans show these kinds of problems, which occur throughout normal aging, result from the normal loss of brain cells in the prefrontal cortex (Milham et al., 2002).

Memory-enhancing products. Americans spend billions on memory-enhancing products, such as ginkgo biloba, which researchers found did NOT improve memory in healthy adults (Solomon et al., 2002). Experts advise the best way to combat age-related memory difficulties is to exercise physically (keep heart healthy) and mentally (engage in cognitive activities like reading, doing crosswords) (G. Cohen, 2006). By consistently engaging in these activities, you may be able to improve your memory 30–40% (B. Gordon, 2007).

Next, we'll learn how the brain changes for the better as we age.

Resiliency

Research indicates that as we age, our brains become more flexible and adaptable. Though brain cells may lose processing speed, their connections to other brain cells multiply and they form more meaningful neural connections as a result of more life experience (Anthes, 2009; McAuliffe, 2008). Also, the brain's left and right hemispheres become better integrated during middle age. This means that brains of older adults can compensate for age-related cognitive declines by expanding their neural network to include both brain hemispheres (G. Cohen, 2006). For instance, by using brain scans, researchers found that older adults who used both brain hemispheres during a memory task performed better than older adults who used only one brain hemisphere (Cabeza et al., 2002). As brains become more flexible and adaptable, they also manage emotions better.

Emotions

Older adults have a "positivity bias," which means that they pay less attention to negative information and more to positive information. Research found that the part of the brain responsible for strong negative emotions (amygdala) becomes less active with age. This focus on the positive explains why older adults have better mental health than younger adults, who mostly focus on negative emotions (Cabeza, 2006, 2008; Carstensen, 2006).

Next, we turn to changes in personality and social development.

C. Personality & Social Changes

Definition

Who am I?

We have discussed many of the major changes that occur during adolescence. One more change is that adolescents develop a sense of who they are, which involves personality and social development.

Personality and ***social development*** refer to how a person develops a sense of self or self-identity, develops relationships with others, and develops the skills useful in social interactions.

Like it or not, this is the real me!

For example, the teenager in the left photo shows her independence and what she believes is her real identity by having a very noticeable hairstyle and piercings.

Personal identity or ***self-identity*** refers to how we describe ourselves and includes our values, goals, traits, perceptions, interests, and motivations.

Personal identity grows and changes as adolescents acquire many new values, goals, beliefs, and interests (Bandura, 1999). A major influence on the kind of identity teenagers develop is how they feel about themselves, which is called self-esteem.

Development of Self-Esteem

What influences self-esteem?

Throughout this module, we have discussed 12-year-old Brandi, who, like other teenagers, has many beliefs and goals, such as being proud to be Black and female, having high hopes for her future, and wanting to be a role model. How Brandi perceives herself, which is called self-esteem, has a significant influence on her developing personality.

Self-esteem is how much we like ourselves and how much we value our self-worth, importance, attractiveness, and social competence.

I'm proud to be Black and female.

For example, in adolescents, self-esteem is influenced by a number of factors, including how ***physically attractive*** and how ***socially competent*** they appear to their peers (DuBois et al., 2000). As teenagers develop sexually mature bodies, they wonder how physically attractive they are; as teenagers begin dating, they wonder how socially skilled they are. Researchers measure changes in adolescents' self-esteem by using longitudinal studies that begin in adolescence and continue through adulthood, such as measuring self-esteem at ages 14, 18, and 23. We'll discuss three different patterns of self-esteem development in adolescents (M. A. Zimmerman et al., 1997).

High Self-Esteem—develop and maintain high levels. A large percentage of adolescents (about 60%) develop and maintain a strong sense of self-esteem through junior high school. These individuals do well in school, develop rewarding friendships, participate in social activities, and are described as cheerful, assertive, emotionally warm, and unwilling to give up if frustrated.

Low Self-Esteem—develop and maintain low levels. A small percentage of adolescents (15%) develop and maintain a chronically low sense of self-esteem that continues through junior high school. These adolescents usually have continuing personal and social problems (shy, lonely, depressed) that have been present for some time and contribute to this low self-esteem.

Reversals—reverse levels. A moderate percentage of adolescents (about 25%) show dramatic reversals in self-esteem, either from high to low or from low to high. For example, some boys change from being stern, unemotional, and lacking social skills into being open and expressive. Researchers think that reversals in self-esteem may result from changes in peer groups, personal attractiveness, or parental relationships.

Next, we'll describe some influences on the development of self-esteem, as well as the importance of self-esteem.

Development and importance of self-esteem. The development of self-esteem in adolescents involves many factors, such as physical attractiveness, acceptance by peers, parental support, media influences, and academic ability (J. M. Connor et al., 2004). In girls, self-esteem is especially dependent on body image and perception of parental support (Polce-Lynch et al., 2001). In boys, self-esteem is especially dependent on looking cool in public, which means not letting stress or anxiety make them look bad (J. Block & Robins, 1993).

Self-esteem has been linked to important positive and negative outcomes. For example, having high self-esteem is associated with positive outcomes, such as being cheerful and happy, having healthy social relationships, and promoting personal adjustment, while having low self-esteem is associated with negative outcomes, such as depression, anxiety, antisocial behavior, and poor personal adjustment (S. L. Murray, 2005; Trzesniewski et al., 2006).

Today's adolescents are a special group of people, or at least they seem to think so. In general, today's teens think quite highly of themselves and believe they will achieve extraordinary success in their personal and work lives. One reason for this shift is that today's parents praise and possibly overpraise their children more than in previous generations (Twenge & Campbell, 2008). Some researchers argue that this heightened self-esteem may lead to depression because of inevitable disappointment, while others believe it will protect teens against feeling the blues (Elias, 2008b).

Self-esteem is important because it influences many aspects of one's personality (Roberts et al., 2002). We'll discuss all aspects and theories of personality in Modules 19 and 20.

There's nothing wrong with us!

One theory of how self-esteem and personal identity develop is found in Erikson's psychosocial stages.

Adulthood: Erikson's Psychosocial Stages

What will I have to deal with?

Adulthood has had ups and downs.

At the beginning of this module, we described how Charlie went from a Hollywood childhood and extraordinary early career success to a middle-aged adult. Along the way, he dealt with dating, getting married, having children, getting divorced, going through drug rehabilitation, and experiencing ups and downs in his career. How these life events might affect Charlie's social and personality development was something Erik Erikson (1982) tried to explain.

As you may remember from Module 17, Erikson divided life into eight ***psychosocial stages,*** each of which contained a unique psychosocial conflict, such as intimacy versus isolation. If Charlie successfully solved each psychosocial conflict, he would develop a healthy personality; if unsuccessful in solving these conflicts, he might develop an unhealthy personality and future psychological problems. In Module 17, we discussed Erikson's stages related to childhood; now, we'll discuss the stages related to adolescence and adulthood.

Stage 5 Identity versus Role Confusion

Period. Adolescence (12–20)

Potential conflict. Adolescents need to leave behind the carefree, irresponsible, and impulsive behaviors of childhood and develop the more purposeful, planned, and responsible behaviors of adulthood. If adolescents successfully resolve this problem, they will develop a healthy and confident sense of ***identity.*** If they are unsuccessful in resolving the problem, they will experience ***role confusion,*** which results in having low self-esteem and becoming unstable or socially withdrawn.

Stage 6 Intimacy versus Isolation

Period. Young adulthood (20–40)

Potential conflict. Young adulthood is a time for finding intimacy by developing loving and meaningful relationships. On the positive side, we can find ***intimacy*** in caring relationships. On the negative side, without intimacy we will have a painful feeling of ***isolation,*** and our relationships will be impersonal.

Stage 7 Generativity versus Stagnation

Period. Middle adulthood (40–65)

Potential conflict. Middle adulthood is a time for helping the younger generation develop worthwhile lives. On the positive side, we can achieve ***generativity*** through raising our own children. If we do not have children of our own, we can achieve generativity through close relationships with children of friends or relatives. Generativity can also be achieved through mentoring at work and helping others. On the negative side, a lack of involvement leads to a feeling of ***stagnation,*** of having done nothing for the younger generation.

Stage 8 Integrity versus Despair

Period. Late adulthood (65 and older)

Potential conflict. Late adulthood is a time for reflecting on and reviewing how we met previous challenges and lived our lives. On the positive side, if we can look back and feel content about how we lived and what we accomplished, we will have a feeling of satisfaction or ***integrity.*** On the negative side, if we reflect and see a series of crises, problems, and bad experiences, we will have a feeling of regret and ***despair.***

Conclusions. Erikson believed that achieving a personally satisfying identity was the very heart and soul of an adolescent's development. As adolescents developed into adults and reached middle adulthood (stage 7), Erikson described a shift from concerns about identity to concerns about being productive, creative, and nurturing (R. Coles, 2000).

Researchers have found evidence that we do go through a sequence of psychosocial stages and that how we handle conflicts at earlier stages affects our personality and social development at later stages (Van Manen & Whitbourne, 1997).

Personality Change

How much will I change?

When Mick Jagger, lead singer of the Rolling Stones, was in his early 20s (below), he boasted, "I'd rather be dead than sing 'Satisfaction' when I'm 45." Now at age 66, Jagger (right) has changed his tune; he and the Stones recently went on a world tour and sang "Satisfaction" dozens of times (L. Ali, 2005; E. Gardner, 2006). As Jagger found out, some of the things that we say and do at 20 may seem stupid at 60. The differences in Jagger at 20 and 60 raise an interesting question: How much do our personalities change and how much do they remain the same?

Researchers answer such questions with longitudinal studies, which measure personality development across time in the same group of individuals. One study found that from adolescence to middle adulthood, individuals became more trusting and intimate and developed a better sense of control and identity. Researchers also found that possessing certain personality traits as a young adult (early 20s) led to developing related traits in middle adulthood (middle 40s). For example, individuals with a high level of identity in their early 20s showed more independence, warmth, and compassion later on in their mid-40s (Vandewater et al., 1997). From these kinds of longitudinal studies researchers draw three conclusions: First, from the end of adolescence through middle adulthood, there are less dramatic but still continuing changes in personality traits, such as becoming more trusting and intimate. Second, possessing certain personality traits in early adulthood is the foundation for developing related traits later on (Roberts et al., 2002). Third, adults appear to pass through psychosocial stages and face conflicts in personality development similar to those proposed by Erikson (Van Manen & Whitbourne, 1997). We'll discuss personality more fully in Modules 19 and 20.

In his 20s, he said he'd rather be dead than singing at 45.

Now in his 60s, Jagger is still touring and singing.

One of the major social and personality changes that women and men go through involves gender roles.

D. Gender Roles, Love & Relationships

Definition: Gender Roles

Why couldn't women be firefighters?

As boys and girls grow to become men and women, they acquire a set of behavioral and cognitive rules called gender roles.

Gender roles are traditional or stereotypical behaviors, attitudes, values, and personality traits that society says are how males and females should think and behave.

You can become aware of gender roles by noticing how differently males and females dress, behave, think, and express emotions. Gender roles played a major part in whether firefighters could be women. Firefighters had always been men because they were considered strong and cool in the face of danger, while women were considered weak and nervous. In the 1970s, when women applied to become firefighters, a local paper warned against the city's "futile exercise in trying to fit women into jobs which common sense tells us are best filled by men." Only after 20 years of political and legal battles were gender roles changed and women allowed to become firefighters (S. Kershaw, 2006).

Women fought for 20 years to become firefighters.

During the past years, there have been some changes in gender roles in the United States. Women can enter careers traditionally reserved for men, such as doctors, police officers, astronauts, and soldiers. And men can enter careers traditionally reserved for women, such as nurses, single parents, and grade-school teachers. We'll discuss some issues surrounding current gender roles and their functions.

Current Gender Roles: U.S. and Worldwide

Each of us acquired a male or female gender role with little conscious effort or awareness, and we often don't notice the effect of gender roles on the development of our personality and social behaviors (Prentice & Carranza, 2002).

U.S. gender roles. The influence of gender roles on personality became clear when researchers asked college students to describe the traits of a typical male and female. Students generally agreed the female gender role included being caring, insecure, emotional, social, and shy. In comparison, students said the male gender role included being arrogant, aggressive, ambitious, not emotional, and dominant (Helgeson, 1994).

The influence of gender roles in the work setting is also undeniably evident. For instance, although an increasing number of women are graduating from top business schools, women fill less than 2% of chief executive jobs at Fortune 500 companies (Creswell, 2006). Researchers do not expect gender equality in high-rank positions to occur any time soon, and there continues to be a wage gap between the sexes, with men earning more than women for the same kind of work (Judge & Livingston, 2008; Kinsman, 2006).

Worldwide gender roles. Not only U.S. college students but also students from around the world agreed that the male gender role included being ambitious, dominant, and independent, while the female gender role included being submissive, affectionate, and emotional (J. E. Williams & Best, 1990). As such, the differences in gender roles are clearly defined because society (family, peers, bosses, and colleagues) encourages and rewards behaviors and thoughts that match expected gender roles and discriminates against those that don't fit in (Eckes & Trautner, 2000).

caring
insecure
helpful
emotional
social
shy

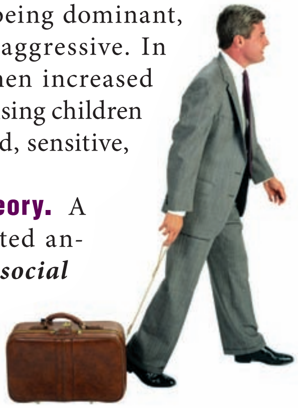
Changes. In the United States, traditional gender roles are becoming less popular. In fact, 60% of men and women report they disagree with the idea that men should earn money and women should take care of children (Jayson, 2009b). Some shifts in gender roles are occurring as early as childhood. For instance, girls are facing increased pressure to not only retain their traditional nurturing behaviors but also excel academically and athletically as much as males (Hinshaw, 2009). The gender role for males is seeing a big change during adulthood. As more and more women pursue careers, today's men are welcoming their role as fathers more than ever. Men's role as active, involved parents is becoming more of the norm than a rarity (L. T. Cullen & Grossman, 2007; Jayson, 2009c).

Why do gender roles develop worldwide, and what are their functions?

Gender Roles: Development and Function

The question of why gender roles develop in every culture has two different but related answers.

Evolutionary psychology theory. One answer from ***evolutionary psychology theory*** emphasizes genetic and biological forces and says that current gender differences are a continuation of the behaviors that evolved from early men and women who adapted these different behaviors to survive the problems of their time (Buss, 1999; Kenrick et al., 2004). According to evolutionary theory, men increased their chances for reproduction by being dominant, controlling, and aggressive. In comparison, women increased their chances of raising children by being concerned, sensitive, and nurturing.



Social role theory. A different but related answer comes from ***social role theory,*** which emphasizes social and cultural influences and states that gender differences between males and females arise from different divisions of labor (Eagly et al., 2004).

arrogant
confident
aggressive
ambitious
unemotional
dominant

These two theories do not disagree but rather emphasize either biological or psychological factors.

Next, you'll see that gender roles affect our expectations about relationships.

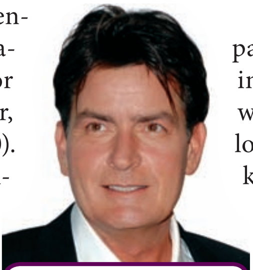
Kinds of Love

Which kind of love are you in?

As we acquire a male or female gender role, we also develop expectations about who we would like for an intimate relationship (G. Fletcher, 2002; G. Fletcher & Simpson, 2000). Once we find someone to experience an intimate relationship with, we may experience different kinds of love.



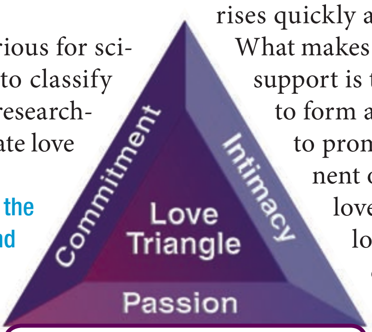
Charlie's experienced different kinds of love.

If we consider Charlie Sheen's history of intimate relationships, we see that as time went by, his expectations for intimate relationships changed. He likely experienced various kinds of love, chose partners for different reasons, and learned some ways to achieve and maintain a successful intimate relationship. Charlie's experiences bring up three issues: kinds of love, choosing a partner, and the characteristics of a long-term commitment.

Earlier researchers had thought love too mysterious for scientific study, but current researchers have begun to classify love into various components. As a starting point, researchers distinguish between passionate and companionate love (Rapson & Hatfield, 2005).

Passionate love involves continuously thinking about the loved one and is accompanied by warm sexual feelings and powerful emotional reactions.

Companionate love involves having trusting and tender feelings for someone whose life is closely bound up with one's own.



Three components of love

For example, when people fall madly in love, it's usually passionate love. When mature couples talk about enjoying each other's company, it's usually companionate love, which may or may not involve sexual behaviors. Thus, love is more complex than many think. One of the better known theories of love is Robert Sternberg's (1999) triangular theory of love.

The ***triangular theory of love*** has three components: passion, intimacy, and commitment. ***Passion*** is feeling physically aroused and attracted to someone. ***Intimacy*** is feeling close and connected to someone; it develops through sharing and communicating. ***Commitment*** is making a pledge to nourish the feelings of love and to actively maintain the relationship.

What makes you feel in love is the component of passion, which rises quickly and strongly influences and biases your judgment. What makes you want to share and offer emotional and material support is the component of intimacy. What makes you want to form a serious relationship, such as getting married, and to promise support through difficult times is the component of commitment. Sternberg believes that the kind of love most of us strive for is complete or consummate love, which is a balanced combination of all three components—passion, intimacy, and commitment.

Sternberg (1999) uses his triangular theory to answer some of the most commonly asked questions about love.

Is there love at first sight?

Love at first sight occurs when we are overwhelmed by passion, without any intimacy or commitment. Sternberg calls this ***infatuated love,*** which can arise in an instant, involves a great deal of physiological arousal, and lasts varying lengths of time. Because there is no intimacy or commitment, infatuated love is destined to fade away.

Why do some people get married so quickly?

Sternberg calls this ***Hollywood love,*** which is a combination of passion and commitment but without any intimacy. In Hollywood love, two people make a commitment based on their passion for each other. Unless they develop intimacy over time, the relationship is likely to fail.

Can there be love without sex?

Sternberg calls love without sex ***companionate love,*** which is a combination of intimacy and commitment without any sexual passion. An example of companionate love is a married couple who are committed to each other and share their lives but whose physical attraction has waned.

Why doesn't romantic love last?

Romantic love, which is a combination of intimacy and passion, usually doesn't last because there is no commitment. As soon as the passion dies and the intimacy fades, the individuals no longer feel in love and go their separate ways.

Brain in Love

Researchers took brain scans of college coeds who had been with their "one true love" for between 2 and 17 months and topped the charts on the passionate love scale (constantly think about their partners, can't sleep, feel euphoric). The coeds were shown photos of their loved ones interspersed with familiar but emotionally neutral faces. Only in response to seeing their loved ones did their brain's ***reward/pleasure center*** (p. 330) show increased activity, similar to the activity seen with cocaine-produced euphoria (Helmuth, 2003a). In comparison, brain scans of partners who had been in longer relationships (average 2 years) indicated activity in additional emotional areas (insula, anterior cingulate) (Fisher, 2003). Researchers concluded that infatuated love primarily activates the brain's reward/pleasure center and turns down activity in brain areas responsible for reason and judgment. In comparison, a more committed love activates additional emotional brain areas, which contributes to forming a longer-lasting relationship (Carey, 2002; C. Miller, 2008).

Researchers can see love in brain scans.

Is it possible for long-married couples to feel the same passion and romance as new love? Common wisdom may say no, but results from brain scans say yes! Researchers found similar brain activity in people who report being in intense love after decades of marriage and in people who only recently fell in love. By using brain scans, researchers also found that people in long-lasting marriages don't experience the obsession and anxiety of new love and instead show more calmness and attachment (Acevedo, 2008a, 2008b).

After choosing a partner and falling in love, the next step is to develop a long-term relationship.

Photo Credit: top, © FilmMagic/Getty Images

D. Gender Roles, Love & Relationships

Choosing a Partner

What am I looking for?

The fact that about 90% of adults in the United States marry means most of us will eventually select a partner for a long-term relationship. However, the fact that 40–60% of new marriages and an even higher percentage of second marriages end in divorce means selecting the right partner can be a difficult and somewhat mysterious process (K. S. Peterson, 2001).

Looking for partner with good earning potential

Researchers suggest that one way we choose a partner for a long-term relationship is by finding someone who matches our ideal-partner schema (G. Fletcher & Simpson, 2000).

A *schema* is an organized mental or cognitive list that includes characteristics, facts, values, or beliefs about people, events, or objects.

An ideal-partner schema is a mental list of the most desirable characteristics we are seeking. An ideal-partner schema in order of preference for unmarried college students (averaged for men and women) is shown at left (Buss, 1994). Results showed men and women form ideal-partner schemas with two major differences: Men rank physical attractiveness as more important, and women rank earning capacity higher (Buss, 1995, 2003).

IDEAL PARTNER

1. kind/understanding
2. exciting
3. intelligent
4. physically attractive (men rank higher)
5. healthy
6. easygoing
7. creative
8. wants children
9. earning potential (women rank higher)

One reason we date different people is to find the ideal partner who best matches the traits on our ideal-partner schema list. However, when we become passionately attracted to a person, our brain's reward/pleasure center is activated and we lose the ability to rationally decide whether a person really has the traits on our list. In this passionate state, we see our person through euphoric, rose-colored lenses that make disagreeable traits temporally disappear. However, such traits will reappear when the euphoric state fades, as it always does (Fisher, 2002).

Looking for partner who is physically attractive

After Mr. or Ms. Right is chosen, the couple is ready to make a commitment, such as living together or getting married.

Cohabiting

Why do couples cohabit?

In the United States, the number of unmarried, heterosexual couples living together, or *cohabiting*, increased from 1 million in 1960 to 13.6 million in 2008 (Jayson, 2005; USCB, 2009b). Fewer unmarried people who cohabit are in homosexual relationships.

The long-standing reason given for why people chose to cohabit was to "test" the relationship. However, this turns out not to be a major reason at all. Instead, most couples report simply wanting to spend more time together as their primary reason to cohabit. Also, high housing costs and tight budgets make living with a dating partner desirable. Additionally, many homosexual couples cohabit due to laws in their states that do not permit them to marry or have civil unions (Jayson, 2009d; Smock, 2005).

What happens within the first two years of living together really matters, as most couples will either break up or marry by then.

More people are choosing to cohabit.

Marriage

Why do marriages last?

Perhaps due to the rising number of people choosing to cohabit with their intimate partner, the average age when men and women get married is increasing (26 for women and 28 for men) (USCB, 2008b). For those who choose to marry, many find long-term happiness and many others find themselves getting a divorce.

To find out why some marriages succeed but about 40–60% fail, researcher John Gottman analyzed videotapes of couples' social interactions and physiological responses over 14 years. Using these data, Gottman's predictions of which couples would stay together and which would divorce were 91% accurate (Gottman, 2003).

Critical factors. As Gottman analyzed couples' social interactions, he found that couples who later divorced had four major problems: One or both partners spent too much time criticizing the other; one or both partners became too defensive when one of their faults was criticized; one or both partners showed contempt for the other; and one or both partners engaged in stonewalling or being unwilling to talk about some problem (Gottman, 2000). The continual stress arising from these problems resulted in couples becoming more unhappy through the years (Gottman, 2003).

Happy relationships. Couples in successful marriages find a way to deal with the four major problems—criticism, defensiveness, contempt, and stonewalling. Successful couples learn to confront and deal with stonewalling by settling disagreements in an open, straightforward way; try to be less defensive about negative feedback; criticize their partners less and try to be more supportive; and agree to overlook small problems they are unlikely to change (Gottman, 1999).

Every couple knows there are ups and downs in marital happiness (right graph) (Benin & Robinson, 1997). Falling in love is grand, but achieving long-term success takes a lots of work (Gottman, 2003).

Satisfaction with Marriage

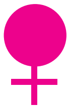
Robinson, cited in *Time*, August 25, 1997, p. 24; List adapted from "Preferences in Human Mate Selection," by D. M. Buss and M. Barnes, 1986, *Journal of Personality and Social Psychology*, 7, 3–15. American Psychological Association.

Concept Review



1. Puberty is accompanied by a number of biological and physical changes, which are triggered by male or female (a) ______________. These chemicals result in the development of male and female secondary (b) ______________ characteristics and, for females, their first menstrual cycle, which is called (c) ______________.

2. The idea that adolescent development consists of a number of cognitive, sexual, social, and personality changes that occur simultaneously is called the ______________ model.

3. Piaget hypothesized that cognitive development is made up of four distinct stages of reasoning, each of which is qualitatively different from and more advanced than the previous one. According to Piaget, from adolescence through adulthood, we are at the ______________ stage, which involves the ability to think about hypothetical concepts, consider an issue from another's viewpoint, and solve abstract problems in a logical manner.

4. New findings indicate that teenagers do not yet have a fully developed part of their brains called the (a) ______________, which has (b) ______________ functions, such as thinking, planning, and making decisions.

5. One reason adolescents engage in more risky behaviors is that they have an underdeveloped (a) ______________ but a fully functioning emotional center, called the (b) ______________

6. The idea that moral reasoning can be classified into three distinct levels and that everyone goes through these levels in order is a theory of moral development proposed by (a) ______________. The level of moral reasoning based primarily on punishment is called (b) ______________; the one based on conforming to laws and society is called (c) ______________; and the one based on balancing rights and laws is called (d) ______________. Most research supports Kohlberg's idea that people do go through (e) ______________ of moral development but not everyone reaches the higher stages.

7. Making impersonal moral decisions, such as keeping the money found in a stranger's wallet, involves areas of the brain associated with retrieving (a) ______________. In comparison, making personal moral decisions, such as keeping the money found in a fellow worker's wallet, involves areas of the brain associated with (b) ______________.

8. The development of independence and achievement during adolescence is shaped by a number of different parenting styles—in particular, (a) ______________, (b) ______________, and (c) ______________—each of which has different costs and benefits to parents and adolescents.

Am I losing my memory?

9. In late adulthood, individuals experience a decline in three cognitive processes: an increase in the time required to respond to some sensory stimulus, which is called the (a) ______________; a decrease in the rate at which we identify some sensory stimulus as different from other stimuli, which is called the (b) ______________; and a decrease in the rate at which we encode information into long-term memory or retrieve it, which is called the (c) ______________ speed.

10. According to Erik Erikson, across our lifetimes we proceed through eight (a) ______________, each of which presents a particular kind of personality or social problem. For adolescents, stage 5 is most relevant and involves (b) ______________ versus role confusion. Finding one's identity has many aspects; the aspect that involves how much we like ourselves and our feelings of worth, attractiveness, and social competence is called (c) ______________. Erikson believed that the most important part of personality development for an adolescent was to achieve a satisfying sense of (d) ______________, while adults are more concerned about being (e) ______________.

11. Males and females think, act, and behave in different ways, and these are called ______________, which are enforced by expectations of parents and peers and by society rewarding traditional roles and punishing roles that are different.

12. One way we select a partner is by forming a mental list of characteristics and then looking for someone who matches our mental list, which is called a ______________.

13. The theory of love that has three components—passion, intimacy, and commitment—is called the ______________.

14. Infatuated love primarily activates the brain's reward/pleasure center and causes feelings of (a) ______________. In comparison, a more committed love activates additional emotional brain areas, which help in forming a longer-lasting (b) ______________.

15. Couples are more likely to have successful long-term relationships if they learn to deal with ______________ in a straightforward way.

Answers: *1. (a) hormones, (b) sexual, (c) menarche; 2. BioPsychoSocial; 3. formal operations; 4. (a) prefrontal cortex, (b) executive; 5. (a) prefrontal cortex, (b) limbic system; 6. (a) Kohlberg, (b) preconventional, (c) conventional, (d) postconventional, (e) stages; 7. (a) information, (b) emotions; 8. (a) authoritarian, (b) authoritative, (c) permissive; 9. (a) reaction time, (b) perceptual speed, (c) processing; 10. (a) psychosocial stages, (b) identity, (c) self-esteem, (d) identity, (e) productive, creative, nurturing; 11. gender roles; 12. schema; 13. triangular theory; 14. (a) euphoria, (b) relationship; 15. conflicts*

E. Research Focus: Happy Marriages

PowerStudy 4.5™

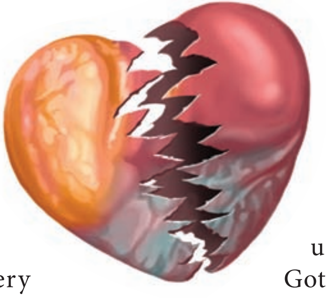
Module 4

E. Limbic System: Old Brain

What's a Love Lab?

What's the key to a successful relationship?

Imagine being a researcher who wants to predict one of the most complex human behaviors: Which couples will succeed and which will fail in long-term relationships? The fact that 40–60% of marriages fail indicates that something is leading to success or failure. How would you design a "love lab," or a research program to figure out what that "something" is?



Every research program aims for the same four goals, which are to describe, explain, predict, and control behavior. The first two goals—describe and explain—are relatively easy. However, the last two goals—predict and control—are very difficult because many human behaviors are so complex that they cannot be completely explained, much less predicted or controlled. Now, along comes psychologist and researcher John Gottman, who claims that not only can he explain the "something" but he can also predict with 91% accuracy which marriages will succeed or fail (Gottman et al., 2006). Since very few human behaviors can be predicted with 91% accuracy, his claim is absolutely amazing.

In the past, researchers used primarily self-reports or questionnaires to study the success or failure of long-term relationships. However, self-reports and questionnaires are not totally reliable, since marriage partners could knowingly (out of embarrassment) or unknowingly (out of defensiveness) bias their answers. Gottman's breakthrough in studying and predicting the success or failure of long-term relationships was to develop a better research method that goes by the zany name of "Love Lab."

Method

In the Love Lab, one partner sits facing the other (photos below). For 15 minutes they discuss a topic that is a known sore point while their facial and physiological responses are recorded.

Facial responses. The advantage of recording each of the partners' nonverbal facial responses is that facial responses reflect a wide range of emotional expressions (surprise, interest, anger, disgust, contempt) that one or both partners may be unaware of or try to deny. Nonverbal behaviors are very important ways of communicating in real life. For example, it's not uncommon for one partner to notice the other partner's facial expression and ask, "What's bothering you?" By recording nonverbal facial cues, which are difficult to hide or fake by normal (untrained) individuals, Gottman can reliably determine whether certain kinds of social interactions cause problems for the partners.

In the Love Lab, a video camera (circled) records facial expressions, and white bands of wires (visible on her fingers and his wrist) record various physiological responses.

Photo Credit: © Andrew Brusso/Corbis Outline

Physiological responses. Gottman also wants to know how long the emotional feelings last. He measures the duration of emotional feelings by recording physiological responses (heart and breathing rate, sweating). These responses reflect the start and duration of increased physiological or emotional arousal, which one or both partners may be unaware of or try to deny. For example, if one or both partners experience frequent and long-lasting bad feelings, it often signals that the marriage is in trouble (Gottman, 1999).

Longitudinal method. So far, you can see that Gottman's Love Lab solved the problem of how to reliably measure a couple's emotional responses and feelings. But how would he know if these measures predicted a marriage's success or failure? To answer this question, Gottman used the longitudinal research method, which means he retested the same couples regularly during 14 years. By retesting the same couples over time, he could determine whether a couple's social interactions and emotional responses recorded during early sessions could be used to predict with 91% accuracy whether this particular marriage would succeed or fail.

Results and Conclusions

After retesting the same 79 couples for 14 years, Gottman (1999) reported that he could predict, based on previous observations in the Love Lab, which of the marriages would succeed or fail. Here are some of the findings that allowed him to predict with such accuracy.

Unsuccessful relationships. We have already discussed the four major problems that couples experience early on and that, if not dealt with successfully, predict failure in long-term relationships. These four problems are giving too many ***criticisms,*** becoming too ***defensive,*** showing ***contempt*** of a partner, and ***stonewalling*** or refusing to settle disagreements in an open, straightforward discussion.

Successful relationships. There are several things that predict successful relationships. First, happy marriages had ***husbands*** who were good at not immediately rejecting their wives' advice but either accepted it or found something reasonable in it. In contrast, unhappy marriages had husbands who were autocratic, failed to listen, and dismissed their wives' advice.

Second, happy marriages had ***wives*** who were careful to express their complaints and advice in gentle, soothing ways, which were easier for their husbands to accept. In contrast, unhappy marriages had wives who phrased their complaints and advice in angry, fighting words that, in turn, triggered equally angry replies from their husbands.

Advice. Gottman's advice is for couples to behave like good friends, which means their relationship should be based on respect, affection, and empathy, and for couples to manage conflicts in gentle, positive ways (Gottman et al., 2006).

Although in the United States most people marry for love, that's not true in other cultures.

F. Cultural Diversity: Preferences for Partners

Measuring Cultural Influences

Can 9,000 people agree?

Imagine being born and raised in a country different from your own, such as Nigeria, Germany, China, Iran, Brazil, Japan, France, or India. Now imagine being asked to list, in order, those traits that you consider most desirable in a potential partner. How much would your culture influence the order of desirable traits? To answer this question, researchers surveyed more than 9,000 young adults (men and women), all in their 20s, who lived in 37 different countries (Buss, 1994; Buss et al., 1990). Subjects were given a list of 32 traits and asked to rank the traits from most to least desirable in a potential partner. The results indicate that 9,000 individuals from many different cultures seemed to agree reasonably well in ranking traits.

What if you were born in Egypt?

Desirable Traits

What is considered desirable in a potential partner? The list on the near right shows the most desirable traits for potential partners averaged across cultures. Men and women have similar lists of desirable traits, as indicated by a high correlation of +0.87 between lists. The numerous similarities between men's and women's lists indicate similar cultural influences.

The list on the far right shows that there were also some interesting differences between men and women. Men almost always ranked physical appearance in a partner higher, while women almost always ranked earning potential in a partner higher.

Average ranking of desirable traits	
1	Kind and understanding
2	Intelligent
3	Exciting personality
4	Healthy
5	Emotionally stable and mature
6	Dependable character
7	Pleasing disposition

How much is virginity valued around the world? In two-thirds of all the cultures measured, men desired virginity or chastity (the lack of previous sexual intercourse) in marriage partners more than women did; there were no cultures where women valued virginity in a prospective partner more than men did (Buss, 1994). For example, in China, virginity is indispensable in a partner; marrying a nonvirgin is simply out of the question (Buss, 1994). People in India, Taiwan, and Iran also placed great value on virginity, while people in the Netherlands, Sweden, and Norway placed little value on virginity in a prospective partner. These differences in the value placed on the virginity of women indicate how cultural influences can raise or lower the desirability of certain traits in potential marriage partners.

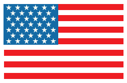
Differences in desirable traits	
8	Good looks (ranked higher by men)
9	Good financial prospect (ranked higher by women)
10	Virginity (ranked higher by men)

Reasons for Marrying

How much is love valued? As the figure on the right shows, cultures in different countries place different values on marrying for love. In the United States and other Western countries, marrying for love is highly valued, but it is valued less in some Middle East, Asian, and African nations.

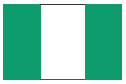
How do women decide? Some anthropologists have argued that women, who invest more time in caring for offspring, would adopt more discriminating standards for potential mates than would men, who invest less time in rearing children. Thus, women would be more careful in deciding whom to marry. This proved true: In nearly every culture, women expressed more stringent standards across a wide range of characteristics (Buss, 1994).

How Citizens in Different Nations Ranked the Importance of Love in Choosing a Spouse



United States: Love ranked **FIRST**, that is, love was the most important factor in choosing a spouse.

Iran: Love ranked **THIRD**, while ranked higher were education, ambition, chastity.



Nigeria: Love ranked **FOURTH**, while ranked higher were good health, refinement, neatness, desire.

China: Love ranked **SIXTH**, while ranked higher were health, chastity, homemaker.

Zulu: Love ranked **SEVENTH**, while ranked higher were mature, emotionally stable, dependable.

How do men decide? Across cultures, men generally decide to marry younger women who are physically attractive. In those societies where men purchase their wives, younger women command a higher bride price. Also, across cultures, the most common reason that men use to dissolve marriages is infertility, or the inability to have children (Buss, 1994).

From surveys of desirable traits in marriage partners, researchers found many similarities across cultures, but they found considerable differences among cultures in reasons for getting married.

We have primarily discussed development in adolescents and young to middle-aged adults. Next, we'll examine the physical changes that come with aging.

G. Physical Changes: Aging

PowerStudy 4.5™

Module 4
B. Neurons: Structures & Function

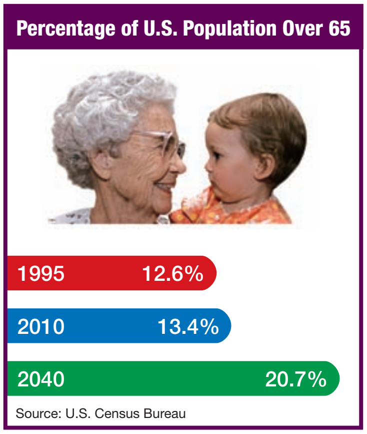
Kinds of Aging

Why do we grow old?

As you look at the photo on the right, the difference you see between grandmother and granddaughter is an example of normal aging, which is very different from pathological aging.

Normal aging is a gradual and natural slowing of our physical and psychological processes from middle through late adulthood.

Pathological aging may be caused by genetic defects, physiological problems, or diseases, such as Alzheimer's (p. 47), all of which accelerate the aging process.



Source: U.S. Census Bureau

One goal of the study of aging, which is called ***gerontology,*** is to separate the causes of normal aging from those of pathological aging. The percentage of people in the United States over 65 is expected to almost double by the year 2040 (left graph). Within 10 years, for the first time in human history, there will be more people over the age of 65 in the world than children under age 5 (USCB, 2008a). Life expectancy in the United States was 45 years in 1945 but is now a record 78 years (WHO, 2009). In the 1920s, only 2,300 people in the United States were over 100, but currently more than 96,000 are over that age and the number is estimated to be 600,000 by 2050 (K. Wright, 2003; USCB, 2009a)!

We'll examine two related questions about aging: Why do our bodies age? How do our bodies and behaviors change with age?

Aging and Physiological Changes

So far, the oldest people on record have lived from 113 to 122 years. How long you will live and how fast your body will age depend about 50% on heredity (genes) and 50% on other factors, such as diet, exercise, lifestyle, and diseases (K. Wright, 2003). In the past decades, the steady increases in life expectancy came primarily from improved public health and new cures for diseases. But advances in controlling diseases are slowing and researchers believe that even with major improvements in geriatric care, the average life expectancy will not go beyond 85 years (Olshansky, 2003). Instead, researchers believe that large increases in life expectancy must now come from slowing the aging process itself (R. Miller, 2003).

The ***aging process*** is caused by a combination of certain genes and proteins that interfere with organ functioning and the natural production of toxic molecules (free radicals), which in turn cause random damage to body organs and DNA (the building blocks of life). Such damage eventually exceeds the body's ability to repair itself and results in greater susceptibility to diseases and death (Olshansky et al., 2002).

Researchers recently found that stress—like that caused by job loss or divorce—results in the aging of DNA, and they are studying the effects meditation and psychotherapy may have on slowing the aging of DNA (Epel & Blackburn, 2004). Animal studies have identified dozens of genes that extended the life span by 200% to 600% (Arantes-Oliveria et al., 2003; Sinclair & Guarente, 2006). Also, human studies have identified a half-dozen genetic factors in the very old (average age 98) that seemed to have slowed the aging process (K. Wright, 2003). Although such practices as having a good diet, exercising, reducing stress, and taking vitamins or antioxidants may improve quality of life and help one live into the 100s, none of these things alone has been shown to slow the aging process and allow humans to live to 130 or beyond (Olshansky, 2003).

As our bodies age, they experience many physiological changes.

Physiological Changes: Early Adulthood

The finding that most athletes peak in their 20s indicates that this is a period of maximum physical ability and capacity. In our early to middle 20s, our immune system, senses, physiological responses, and mental skills are at their peak efficiency.

Middle Adulthood

In our 30s and 40s, we usually gain weight, primarily because we are less active. By the late 40s, there is a slight decrease in a number of physiological responses, including heart rate, lung capacity, muscle strength, and eyesight.

Late Adulthood

In our 50s and 60s, we may experience a gradual decline in height because of loss of bone, a further decrease in output of lungs and kidneys, an increase in skin wrinkles, and a deterioration in joints. Sensory organs become less sensitive, resulting in less acute vision, hearing, and taste. The heart, which is a muscle, becomes less effective at pumping blood, which may result in as much as a 35% decrease in blood flow through the coronary arteries. A general decrease occurs in both the number and diameter of muscle fibers, which may explain some of the slowing in motor functions that usually accompanies old age.

Very Late Adulthood

In our 70s and 80s, we undergo further decreases in muscle strength, bone density, speed of nerve conduction, and output of lungs, heart, and kidneys. More than 10% have Parkinson's or Alzheimer's disease.

As many of the body's physical responses slow down with aging, there are corresponding decreases in related behaviors. Earlier in this module we discussed decreases in memory with aging (p. 415), and now we'll discuss decreases in sexual behavior.

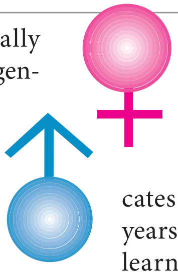
Sexual Changes with Aging

How does sex change with aging?

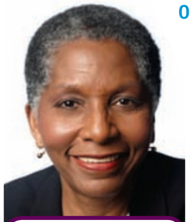


Surveys of sexual behavior, which usually sample people between ages 17 and 59, generally report that single men have more sex partners, experience orgasm more frequently, and masturbate more frequently than single women and that about one-third of married couples have sex two or three times a week (Crooks & Baur, 2002). People in late adulthood (60–80) are often not included in these surveys because of the common stereotype that they no longer have any interest in sexual activity or that it is inappropriate for them to engage in sex. However, a survey of men and women over age 70 found that about 57% of men and 52% of women were sexually active (Beckman et al., 2008). This survey indicates that adults can enjoy sexual activity well into their later years, especially if they know how sexual responses change and learn ways to deal with these changes. We'll discuss some of the normal changes in sexual responses that accompany aging.

Sexual Changes in Women

The most significant effect on women's sexual behavior in later adulthood is menopause.

Menopause occurs in women at about age 50 (range 35–60) and involves a gradual stoppage in secretion of the major female hormone (estrogen), which in turn results in cessation of both ovulation and the menstrual cycle.



Menopause is not the end of sexual behavior.

During and immediately after menopause, 15% of women experience physical symptoms severe enough to require medical help; 65% experience mild symptoms that do not require medical help; and 20% have few if any physical symptoms (Hooyman & Niyak, 1999).

Physical Symptoms

Most women experience hot flashes, some sleep disturbance, and dryness of the vagina, which result from a decrease and eventual stoppage in the secretion of the female hormone estrogen. A lack of estrogen results in thinning of the vaginal wall and reduction of lubrication during arousal. However, there is little or no change in the ability to become sexually aroused or to reach orgasm. Potential problems with lack of lubrication or painful intercourse may be treated with hormone replacement therapy, which has benefits and risks (L. Nathan & Judd, 2007; S. D. Reed & Sutton, 2006), or the use of vaginal creams. Because researchers find no correlation between decreased levels of hormones and sexual activity, women's continued sexual activity after menopause is affected primarily by psychological rather than physiological factors (Crooks & Baur, 2002; J. Potter, 2006).

Psychological Symptoms

Researchers followed 400 healthy women through menopause and observed many psychological changes. They found that women did report psychological symptoms, such as depression, anxiety, and anger. However, these symptoms were related to other stressful issues (e.g., growing older in a society that glorifies being young), rather than to the physical symptoms of menopause. In addition, women's expectations influenced their psychological outlook during menopause. Women with positive expectations about what they hope to accomplish have few psychological symptoms, compared to women who expect their lives to be over and thus feel depressed during menopause (Dennerstein et al., 1997; Neugarten, 1994).

Sexual Activities

Some older women think sexual activity is appropriate only for young people. Others expect sexual activity to be just like it was during their young adulthood, and they may have difficulty accepting the inevitable changes that occur as they age. Some aging couples report sexual relationships become more satisfying over time, but others say sexual activity becomes boring and predictable. Overall, half of women age 50 and older are at least as satisfied with their sex life as during their younger years (J. Potter, 2006). But many women do experience sexual difficulties and often find it difficult to discuss with others. One way to help these women is to have their doctors ask them about their sexual functioning; currently, more than 90% of doctors are reported to not bring up the topic (WSHF, 2008).

It is interesting that women in cultures where menopause results in increased social status look forward to menopause and have fewer symptoms than women in the United States (Richters, 1997).

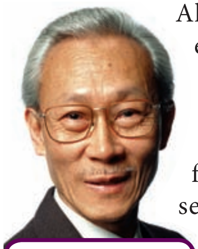
Sexual Changes in Men

As men reach late adulthood (60s, 70s, and 80s), they may experience some physiological changes that decrease sexual responsiveness.

Sexual Responding

Because many of the body's physiological responses slow down, older men may require more time and stimulation to have an erection and to reach orgasm. Upon ejaculation, there may be a reduction in the force and amount of fluid. However, healthy men usually have no difficulty in becoming sexually aroused or reaching orgasm. Some men worry that their decreased ability to have an erection or reach orgasm means an end to their sexuality (Masters & Johnson, 1981). Currently, there are a few drugs (such as Viagra—p. 356) approved for the treatment of impotency, which is the inability to have an erection. These drugs help about 70% of men who have impotency problems (Berenson, 2005).

Psychological Problems



Some things may take longer, but that's OK.

Although older men are generally more sexually active than older women, their decreased sexual abilities can make them uncomfortable and threaten their self-esteem. However, having longer periods of stimulation, improving intimate communication, and using more imaginative sexual activity can usually compensate for men's decreased self-confidence (Bartlik & Goldstein, 2001). Health experts counsel that as we grow older, we should learn new skills, such as being more understanding and sensitive to our partner's needs, which will help maintain sexual enjoyment (Crooks & Baur, 2008).

Next, we'll discuss a serious problem that is shared by both adolescents and seniors, a high rate of suicide.

Photo Credits: both, © PhotoDisc, Inc.

H. Application: Suicide

Teenage/Young Adult Suicide

What is a major, preventable cause of death?

Suicide is a major, preventable leading cause of death. In the United States alone, a person dies by suicide every 17 minutes and someone attempts suicide every minute (CDC, 2006d; Ezzell, 2003). The suicide rate across all ages is 10.9 per 100,000. Among teens and young adults, the suicide rate is 10.4 per 100,000. People over 65 have a higher rate of suicide (14.2 per 100,000) (NIMH, 2009b).

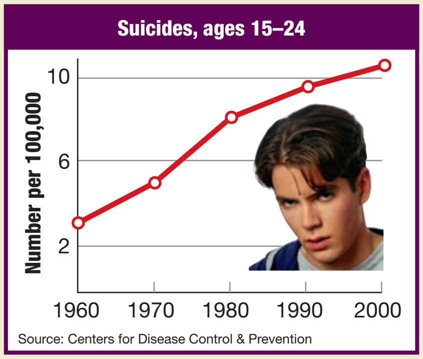
We'll first discuss issues related to teenage/young adult suicide and then look at suicide in the elderly. We'll begin with four real-life teenage examples that illustrate how complex the issues and causes are. In a span of five weeks, four teenage boys—one a straight-A student, one the class clown, one deeply religious person, and one very troubled boy—committed suicide in the small southern town of Sheridan, Arkansas (adapted from *People,* May 21, 1990, pp. 56–59). Here are their sad and tragic stories.

1 March 28, 1990: Raymond, 17 Years Old

According to the police chief, Ray had threatened to kill himself in the past, but the threats were considered teenage histrionics. He had a drinking problem, had been arrested for drunken driving, and had been sent to a rehabilitation center for several weeks. Before Ray shot himself, however, his life seemed to be improving, and he had made plans to go to college. A suicide note to his girlfriend said, "Don't blame yourself. It's nobody's fault."

2 April 30, 1990: Tommy, 16 Years Old

His teenage peers considered Tommy a clown, but his best friend, Rhonda, didn't believe that. She thought Tommy's clever wit and clowning were a mask for his insecurity. On April 29, Tommy called Rhonda, which he did regularly, and told her that he was going to kill himself. Certain he would not carry out his threat, she made him promise to come to school the next day. Tommy came to school, and in one of his classes he got up and stated that he had two things to say. He said that he loved Rhonda, although they had never dated. "The other thing," he said, "is this." He pulled out a pistol and shot himself.



Source: Centers for Disease Control & Prevention

3 April 30, 1990: Thomas, 19 Years Old

Thomas was a straight-A student who liked to read, listen to oldies, and hunt and fish. He did not drink, smoke, or swear. He lived too far out of town to have many buddies. His father had died when he was 9. Two years earlier, his grandfather, who had terminal cancer, committed suicide with a pistol to his head. Tommy had shot himself in the afternoon, and that very night Thomas did the same. In his suicide note he said, "Where shall I begin? I really don't know. It's hard to say what's going on anymore. A long time now I have felt like I am on the edge and slipping fast. I guess I've finally slipped over the edge."

4 May 2, 1990: Jerry, 17 Years Old

Jerry's suicide was the last of the four and the most troubling. He was popular, gregarious, good-looking, and so deeply religious that he was nicknamed "preacher boy." The night after Tommy's suicide he told his mother, "I can't understand how anyone would commit suicide—that was the coward's way." That same night he called his girlfriend and said, "I love you. I'll talk to you tomorrow." The next day he stayed home from school, and around noon he shot himself in the head. The family insists that Jerry's death was accidental.

Problems Related to Suicide

Why do teens take their own lives?

Notice that in the above examples, family and friends could not believe that two of the four adolescents would ever even think of committing suicide. That's because one was a straight-A student and the other was very popular and deeply religious. In the other two cases, one adolescent had said he was thinking about suicide and one had made a previous attempt. Thus, if and when adolescents talk about committing suicide, parents and friends need to take such talk seriously. In other cases, the problems, symptoms, or events leading up to or triggering suicide may be difficult to recognize. However, clinicians find that the following problems may lead to or trigger suicide attempts.

Problems: helplessness, depression, drugs

Problems and symptoms. The most common ***psychological problems*** include depression, feelings of helplessness, and drug-related problems, such as Raymond's alcohol problem. Usually these problems have persisted for some time (Haliburn, 2000). The most common ***behavioral symptoms*** include decline in school performance; social isolation and withdrawal; intense difficulties with parents, siblings, and peers; and antisocial behavior (Mayo Clinic, 2006b). For example, Thomas's suicide note says, "A long time now I have felt like I am on the edge and slipping fast."

Precipitators. In most cases, there are ***precipitators*** of suicide, which may be certain events, feelings, or situations. For example, common precipitators include problems with relationships, bouts of depression, drinking problems, and relatively ordinary stressors, such as difficulties with dating, parents, or school. A high percentage of victims had either expressed the wish to die or threatened suicide, as was true for both Raymond and Tommy (Mayo Clinic, 2006b).

One reason parents and friends are shocked by a teenager's or young adult's suicide is that the problems or precipitators may be hard to spot.

Photo Credits: © PhotoDisc, Inc.

Preventing Suicide

How can suicide be prevented?

We've learned that suicide is a major leading cause of death among youth and adults. It is also a preventable public health problem. Therapists have proposed a three-step program to help identify risk factors and ultimately prevent suicide.

Identify Risk Factors

"I'm depressed and heartbroken, and my parents are divorcing."

The first step is to identify the risk factors, which include mood disorders, drug abuse, previous suicide attempt, suicide of a friend, and major life stressors, such as family turmoil or parental separation. A youth with one or more of these risk factors is considered to be in great danger of committing suicide (Mayo Clinic, 2006b). Researchers are now finding that the brains of suicide victims differ from other brains in several ways (such as lack of specific chemical receptors in decision-making areas of the brain), which indicates that some type of biological imbalance is a risk factor for suicide (Wenner, 2009). Identifying risk factors may involve reports from peers and family members, programs on suicide prevention in schools, 24-hour hotlines, and medical tests.

Psychiatric Evaluation and Psychosocial Intervention

After parents, peers, or teachers identify one or more risk factors, the next step is a thorough medical and psychological evaluation of the individual as well as interviews with the individual's family members—with each family member being assured of confidentiality (Weller et al., 2001). Based on such information, a treatment plan is developed. In the short term, (1) a contract is negotiated so that the person will not harm him- or herself, (2) lethal means are removed from the home (guns and drugs), and (3) support and a 24-hour contact are provided. In the long term, the individual's personal problems are addressed, which may include help with improving his or her self-image and developing better interpersonal skills and functioning. Because most suicidal teenagers/young adults also have serious psychological problems (depression, loneliness, anxiety), psychotherapy and psychiatric medication are usually needed (Fristad & Shaver, 2001).

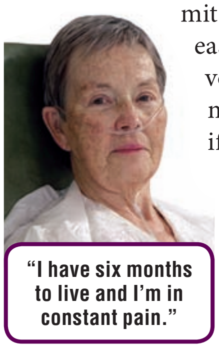
Although teenagers/young adults have a relatively high rate of suicide, the highest rate is found in a group of people you might never expect: the retired, 65-and-over group.

Suicide in the Elderly

Why are rates so high?

Suicide rates in the elderly increase with age, from 14 per 100,000 for individuals aged 65–74 to as high as 48 per 100,000 for those 85 and older (NIMH, 2009). Several risk factors contribute to this high rate of suicide.

Risk factors. The common risk factors for suicide among the elderly include serious health problems, stressful life events, loneliness, and especially depression, which is present in about 90–95% of those who commit suicide (Cavanagh et al., 2003). There is also a growing trend of murder-suicide, in which one member of an elderly couple kills the other and then takes his or her own life. Murder-suicides in the elderly account for about 2,500 deaths a year (Sharp, 2003).



"I have six months to live and I'm in constant pain."

Assisted suicide. Recent polls indicated that although only 12% of those surveyed said suicide was morally acceptable (Sharp, 2003), 46% said a doctor should be allowed to help a person "commit suicide" provided that person has a painful and incurable disease (C. L. Grossman & Nichols, 2006). In the late 1990s, Oregon voters twice approved an assisted suicide law, which allows a mentally competent patient to request a lethal dose of drugs if at least two doctors determine that the person has less than six months to live. By 2005, 326 people had obtained lethal prescriptions and, of these, 208 people (about equal numbers of men and women), most suffering from cancer, took their own lives as allowed by Oregon's law (C. L. Grossman & Nichols, 2006). Assisted suicide is currently legal in the Netherlands, Belgium, and Switzerland (CBS News, 2004b).

Opponents of Doctor-Assisted Suicide

Opponents include religious groups that believe taking one's life should never be sanctioned, others who think doctors should not be involved in helping people take their own lives, and those who fear caretakers may coerce vulnerable people into assisted suicide to reduce the financial burden of caring for them (CBS News, 2004b; Verhovek, 2002). For example, making assisted suicide easier may increase the chances that people who are suffering from mental problems or temporary emotional difficulties will take their own lives without exploring other possibilities for living.

Proponents of Doctor-Assisted Suicide

Proponents explain that each of us has the moral right to end our life if we decide that life has become unbearable for health reasons (CBS News, 2004b). The *New England Journal of Medicine* published an article by a group of doctors who proposed a policy of legalized physician-assisted death with safeguards to protect patients, preserve the integrity of physicians, and ensure that voluntary physician-assisted death occurs only as a last resort (F. G. Miller et al., 1994). Researchers reviewed the effects of Oregon's assisted suicide law and concluded that there have not been any of the abuses or problems feared by opponents and that most of the individuals who chose doctor-assisted suicide were well-educated, mostly elderly cancer patients who had health insurance and were concerned about loss of bodily functions and increasing pain (Wineberg & Werth, 2003).

The pros and cons of doctor-assisted suicide will continue to be debated, especially since the elderly population will almost double in the next 35 years.

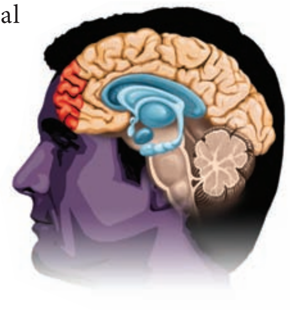
Summary Test

A. Puberty & Sexual Behavior

1. Girls and boys experience three major biological changes as they go through a period called (a) ________________. For both girls and boys, one of these changes is the development of (b) ________________ maturity, which for girls includes the first menstrual cycle, called (c) ________________, and for boys includes the production of sperm. These physical changes in girls and boys are triggered by a portion of the brain called the (d) ________________. A second change is the development of (e) ________________ sexual characteristics, such as pubic hair and gender-specific physical changes. A third change is a surge in (f) ________________ growth, especially height. The changes for girls tend to start about two years earlier than those for boys.

B. Cognitive & Emotional Changes

2. Piaget's fourth cognitive stage, which begins in adolescence and continues into adulthood, is called the (a) ________________ stage. During this stage, adolescents and adults develop the ability to think about (b) ________________ concepts, plan for the future, and solve abstract problems. One reason adolescents engage in more risky behaviors is that they have an underdeveloped (c) ________________ but a fully functioning emotional center, called the (d) ________________.



3. According to Kohlberg's theory, moral reasoning can be classified into three distinct levels, and everyone progresses through the levels in the same order. However, not all adults reach the higher stages. The first level, the (a) ________________ level, has two stages. In stage 1, moral decisions are determined primarily through fear of punishment, while at stage 2 they are guided by satisfying one's self-interest. The second level, the (b) ________________ level, also has two stages. In the first of these, stage 3, people conform to the standards of others they value; in stage 4, they conform to the laws of society. In the third level, the (c) ________________ level, moral decisions are made after thinking about all the alternatives and striking a balance between human rights and the laws of society.

4. Making impersonal moral decisions, such as keeping the money found in a stranger's wallet, involves areas of the brain associated with retrieving (a) ________________. In comparison, making personal moral decisions, such as keeping the money found in a fellow worker's wallet, involves areas of the brain associated with (b) ________________.

5. Parenting styles affect many aspects of adolescents' development. Parents who attempt to shape and control their children in accordance with a set standard of conduct are termed (a) ________________. Parents who attempt to direct their children's activities in a rational and intelligent way and are supportive, loving, and committed are called (b) ________________. Parents who are less controlling and behave with a nonpunishing and accepting attitude toward their children's impulses are called (c) ________________.

C. Personality & Social Changes

6. How you describe yourself, including your values, goals, traits, interests, and motivations, is a function of your sense of (a) ________________, which is part of the problem to be faced in stage 5 of Erikson's eight (b) ________________ stages. Those who are unsuccessful in resolving the problems of this stage will experience (c) ________________, which results in low self-esteem, and may become socially withdrawn.

7. An adolescent's feeling of worth, attractiveness, and social competence is called ________________, which is influenced particularly by physical appearance, social acceptability, and management of public behaviors (anxiety and stress).

8. The challenges of adulthood are covered in the last three of Erikson's eight (a) ________________ stages. According to his theory, in stage 6, young adults face the problems of intimacy versus (b) ________________. In stage 7, middle adults face problems of generativity versus (c) ________________. In stage 8, older adults reflect on their lives; if they feel positive and content about how they lived and what they accomplished, they will have a feeling of satisfaction or (d) ________________; if not, they will have a feeling of regret and (e) ________________.

D. Gender Roles, Love & Relationships

9. During childhood and adolescence, males and females experience pressures and expectations from parents, peers, and society to behave in different ways. These expected patterns of behavior and thought, called ________________, influence cognitive, personality, and social development.

10. The kind of love that involves continually thinking about the loved one and is accompanied by sexual feelings and powerful emotional reactions is called (a) ________________ love. The kind of love that involves trusting and tender feelings for someone whose life is closely bound up with one's own is called (b) ________________ love. Sternberg's triangular theory of love

has three components: feeling physiological aroused and attracted is (c) ________, feeling close and committed is (d) ________, and pledging to nourish feelings is (e) ________. Infatuated love primarily activates the brain's (f) ________ and causes feelings of euphoria. In comparison, a more committed love activates additional (g) ________ brain areas, which help in forming a longer-lasting relationship.

11. One way that we select a mate is by developing an organized mental list of desirable characteristics and then looking for someone who matches this mental list, which is called a ________.

E. Research Focus: Happy Marriages

12. Gottman identified four problems that can result in the failure of a long-term relationship: these problems involve (a) ________, ________, ________, and ________. In successful marriages, wives learn to express their (b) ________ in gentle ways so their husbands are more likely to listen and accept, and husbands learn not to reject their wives' (c) ________ without listening and finding something reasonable in it.

F. Cultural Diversity: Preferences for Partners

United States: Love ranked **FIRST**, that is, love was the most important factor in choosing a spouse.

Iran: Love ranked **THIRD**, while ranked higher were education, ambition, chastity.

13. People's lists of desirable traits for a mate show remarkable similarity across cultures. However, there are some differences in ranking between the genders; for example, men rank (a) ________ higher than women do, and women rank (b) ________ higher than men do. Also, different cultures place different values on the desirability of marrying someone who is a (c) ________ and marrying someone primarily because of being in (d) ________.

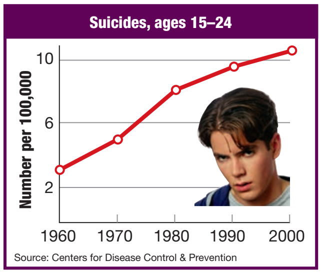
G. Physical Changes: Aging

14. The gradual and natural slowing of our physical and psychological processes from middle through late adulthood is called (a) ________ aging. This process occurs when certain (b) ________ and ________ interfere with organ functioning and when the natural production of toxic (c) ________ (free radicals) causes random damage to body organs and to DNA (the building blocks of life). This aging process, which decreases the effectiveness of sensory and body organs, eventually exceeds the body's ability to repair itself and results in greater susceptible to (d) ________.

15. If the aging process is caused by genetic defects, physiological problems, or diseases, it is called ________ aging, an example of which is Alzheimer's disease.

16. In later adulthood (about age 50), women experience a gradual reduction in the secretion of estrogen, which results in cessation of ovulation and the menstrual cycle; this is called (a) ________. In late adulthood (60–80), men do not stop producing testosterone, but they may experience a decrease in sexual responsiveness due to (b) ________ changes.

H. Application: Suicide



Source: Centers for Disease Control & Prevention

17. A number of factors have been found to be related to teenage suicide. Before committing suicide, adolescents usually have a number of (a) ________ problems, such as depression, feelings of helplessness, or drug-related problems; adolescents also show a number of (b) ________ symptoms, such as falling grades, social isolation and withdrawal, difficulties with family and peers, and antisocial behavior. Usually, suicide is preceded by events or feelings called (c) ________; these may include problems with relationships or bouts of depression or drinking.

18. Among the risk factors for suicide in the elderly are depression and loneliness, but the major contributing cause is (a) ________ problems. Currently, there is considerable discussion in the United States over the right of a person with a terminal disease to end his or her life through (b) ________ suicide.

Answers: *1. (a) puberty, (b) sexual, (c) menarche, (d) hypothalamus, (e) secondary, (f) physical; 2. (a) formal operations, (b) abstract or hypothetical, (c) prefrontal cortex, (d) limbic system; 3. (a) preconventional, (b) conventional, (c) postconventional; 4. (a) information, (b) emotions; 5. (a) authoritarian, (b) authoritative, (c) permissive; 6. (a) identity or self, (b) psychosocial, (c) identity confusion; 7. self-esteem; 8. (a) psychosocial, (b) isolation, (c) stagnation, (d) integrity, (e) despair; 9. gender roles; 10. (a) passionate, (b) companionate, (c) passion, (d) intimacy, (e) commitment, (f) reward/pleasure center, (g) emotional; 11. schema; 12. (a) criticism, defensiveness, contempt, stonewalling, (b) complaints, (c) advice; 13. (a) good looks, virginity, (b) financial prospects, (c) virgin, (d) love; 14. (a) normal, (b) genes, proteins, (c) molecules, (d) disease and death; 15. pathological; 16. (a) menopause, (b) physiological; 17. (a) psychological, (b) behavioral, (c) precipitators; 18. (a) health or medical, (b) assisted*

Critical Thinking

Are Teens Too Young to Drive?

Car crashes are the No. 1 cause of death and disability for teens, killing more than 5,000 a year and injuring 300,000 more. Teenage drivers are about four times more likely to crash than older drivers and three times more likely to die in a crash. The risk of crashes is highest for 16-year-olds; one in five will have a car crash within the first year of driving.

The possibility of raising the legal driving age has been receiving increasing attention. Proponents argue that teens are too immature to handle the responsibility of driving. In fact, a recent national survey found that nearly two-thirds (61%) of people believe that a 16-year-old is too young to have a driver's license, and more than half (53%) think teens should be at least 18 to obtain a driver's license. Opponents of raising the legal driving age argue that responsible teen drivers should not be punished for the mistakes of careless teens causing accidents.

The opinion of the majority of Americans about teens being too young to drive is supported by scientific findings. Brain researchers report the "executive branch" of the teen brain—the part that considers risks and consequences, makes judgments, and controls impulsive behavior—is not fully developed until age 25 and is far less developed in 16-year-olds than in older teens. Driving is especially dangerous because the teenage years are filled with a huge rush of hormones that encourage thrill-seeking and risk-taking behaviors. For instance, when a teen drives 15–20 mph over the speed limit, the part of the brain that processes a thrill works fine, but the part that warns of dangerous consequences is essentially useless. Psychologist Laurence Steinberg describes the dangers of teen driving by saying, "It's like turning on the engine of a car without a skilled driver at the wheel" (Wallis & Dell, 2004).

A contributing factor to teens' poor judgment is that they don't understand well-established risky driving behaviors are dangerous. For instance, only 28% of teens reported using a cell phone is a risk; only 10% said having other teens in the car is a distraction while driving; and only 50% reported not wearing a seat belt or speeding is dangerous. All these things place drivers in serious risk of harm.

Several states have already imposed restrictions on 16-year-old drivers, such as prohibiting late-night driving and limiting the number of passengers they are allowed to have in their car. But, how far should lawmakers go to reduce the dangers of teen drivers? Jeffrey Runge, an emergency room doctor, has treated many teen crash victims and makes it clear that lawmakers should take the dangers of teenage drivers very seriously: "If we had any other disease that was wiping out our teenagers at the rate of thousands per year, there would be no end to what we would do as a society to stop that" (Stafford, 2005). (Adapted from Associated Press, 2006d; Brophy, 2006; R. Davis, 2005; Henderson, 2006; L. Lyon, 2009; O'Donnell, 2005; Stafford, 2005; Vetter, 2008; Wallis & Dell, 2004; Williamson, 2005)

QUESTIONS

1 Besides traffic accidents, what are other costs or dangers of teen driving?

2 What immature teen characteristics may contribute to their irresponsible driving?

3 What other irresponsible teen behaviors may be a result of an "executive branch" that is not yet fully developed?

4 What part of the brain is responsible for thrill-seeking and risk-taking behaviors?

5 What are some factors that are not specific to teens that increase the probability of getting into a car accident?

6 Are stricter laws the solution to reducing the dangers of teen driving?

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Typical families with teen drivers spend $20,000 total during the first three years of teen driving, and if their teen crashes, the amount increases to $25,000. Teen crashes result in a hefty economic cost of over $40 billion a year. Also, let's not forget the thousands of innocent drivers and passengers who die or get injured as a result of careless teen driving.
2. Teenagers are known to make poor judgments, act impulsively, and take great risks. Common immature teen characteristics include excessive socializing, feelings of invulnerability, and a susceptibility to get easily distracted, all of which may contribute to reckless driving.
3. Some irresponsible teen behaviors that result from an underdeveloped executive branch include using drugs, having unprotected sex, bullying or fighting, stealing, not wearing a seat belt, and dropping out of school.
4. Sex hormones secreted during puberty increase the growth of the limbic system, which is believed to account for teenagers' thrill-seeking and risk-taking behaviors, as well as their moodiness.
5. Numerous factors increase the likelihood of even a seasoned driver getting into an accident. Some examples are road construction, poor visibility (fog), slippery roads (rain, snow), using a phone while driving, fatigue, tailgating, rubbernecking, applying makeup, and using an electric razor.
6. Stricter restrictions on teen driving can help only so much because the brains of teens are simply not mature yet. Still, laws that impose strict conditions for a teen to obtain a driver's license can reduce fatal crashes involving 16-year-olds by up to 21%.

Personality

How did he become a deceiver and a liar?

Ted Haggard founded New Life Church in the basement of his house 25 years ago and became a prominent author and national evangelical Christian leader with a congregation of 14,000 worshippers in the largest church in Colorado. He is married with five children and has boyish dimples and a warm smile.

In 2006, at the peak of his career, a male prostitute accused Haggard of having a three-year sexual affair with him and of using drugs. This accusation was alarming not only because Haggard was a married pastor, but also because he publicly supported a constitutional amendment banning gay marriage.

At the height of his career, Ted Haggard, well-known pastor, confessed to "sexual immorality."

When the accusations were first broadcast on the news, Haggard confessed to church officials, saying, "Ninety-eight percent of what you know of me was the real me. Two percent of me would rise up, and I couldn't overcome it" (Haggard, 2006a). Then, in a television news interview the next morning, Haggard denied ever having sex with a male prostitute and ever using drugs. Church officials were shocked and appalled when they saw the other side of Ted during the interview as he lied while still smiling at the camera, appearing calm and assured.

As evidence of Haggard having sexual encounters with a male prostitute and using drugs continued to build, he made the following public confession: "The fact is that I am guilty of sexual immorality… I'm a deceiver and a liar. There is part of my life that is so repulsive and dark that I've been warring against it all of my adult life" (Haggard, 2006a). Haggard resigned as president of the 30-million-member National Association of Evangelicals and was dismissed as senior pastor of New Life Church. In less than 24 hours, everything Haggard had worked so hard for during the past 25 years quickly slipped away from him.

Figuring someone out involves examining the puzzling, fascinating, and complex components of our innermost selves, our personalities.

Personality **refers to a combination of long-lasting and distinctive behaviors, thoughts, motives, and emotions that typify how we react and adapt to other people and situations.**

Haggard's moral public persona and dark private self raise a number of questions about personality: How does personality develop? Why do personalities differ? How well do we know ourselves? These kinds of questions are explored by theories of personality.

A *theory of personality* is an organized attempt to describe and explain how personalities develop and why personalities differ.

On the one hand, personality theories try to explain why Haggard's personality ended his career as an evangelical pastor. On the other hand, personality theories also try to explain why some individuals have personalities that help them overcome horrendous problems and achieve personal success. One such individual is Charles Dutton.

Changing Personality

How did he change from a criminal to an actor?

Charles Dutton had been in and out of reform schools since he was 12 years old and was finally sent to prison for manslaughter and illegal possession of a firearm. While in prison, he got into trouble for being a ringleader of a riot and was punished with solitary confinement. To pass his time, he took along a friend's book of plays by black authors. Dutton was so moved by the plays' messages that for the first time he thought about channeling his rage and anger into acting.

At one point he spent more than 60 painful days in the prison hospital after a fellow inmate had plunged an ice pick through his neck. During those long days in the hospital, Dutton decided that it was time to put his life in order and accomplish something worthwhile during his remaining time in prison. He obtained a high school equivalency certificate and then a two-year college degree, read dozens of plays, and even started a prison theater. After his parole, he attended college and got his B.A. in drama. His high point came when he was accepted into Yale drama school.

By the early 1990s, ex-problem boy, ex-con, ex-prisoner Charles Dutton (right photo) had turned into a very successful actor and starred in his own television series. He has since gone on to star in and direct movies (S. King, 1991; M. Schneider, 2007). Dutton's story is an emotionally painful search for identity, culminating in the discovery and development of his acting potential. We'll discuss a theory of personality that emphasizes the development of our full potential.

Charles Dutton, formerly a convict and violent prisoner, became a respected actor and director.

What's Coming

We'll discuss two very different theories of personality: Sigmund Freud's psychodynamic theory emphasizes unconscious forces, irrational thoughts, and the lasting impressions of childhood experiences, whereas humanistic theories emphasize our rational processes and our natural striving to reach our true potentials.

We'll begin with a look at Ted Haggard's problems and where his inner demons came from.

Photo Credits: left, © Dennis Oda; right, © Fox/Yorma Kahana/Shooting Star

A. Freud's Psychodynamic Theory

Definition

Why sexual immorality at age 50?

Freud's theory of personality begins with a controversial assumption that is an important key to unlocking the secrets of personality. To understand how Freud found this key idea, we'll journey back in time to the late 1800s.

At that time, Freud was wondering why several of his women patients had developed very noticeable physical symptoms, such as losing all sensation in their hands or being unable to control the movements of their legs. What most puzzled Freud, who was a medical doctor, was that despite these obvious physical complaints, he could not identify a single physical cause for these symptoms. Somehow, Freud's brilliant mind solved this problem and, in so doing, found an important key to unlocking the secrets of personality. Freud reasoned that since there were no observable physical or neurological causes of the women's physical symptoms, the causes must come from unconscious psychological forces (Westen & Gabbard, 1999).

Freud would say childhood experiences and unconscious forces played a role in Ted Haggard's "sexual immorality."

In the 1800s, Freud's belief that human behavior was influenced by unconscious psychological forces was revolutionary, and it led to his equally revolutionary theory of personality.

***Freud's psychodynamic theory of personality* emphasizes the importance of early childhood experiences, unconscious or repressed thoughts that we cannot voluntarily access, and the conflicts between conscious and unconscious forces that influence our feelings, thoughts, and behaviors.**

Freud believed not only that unconscious psychological forces had a powerful influence on personality but also that these forces originated in early childhood. If Freud were alive today, he would look for reasons behind Ted Haggard's self-confessed "sexual immorality" at age 50 by searching through Ted's childhood and his unconscious thoughts and forces. Here's what Freud would find.

Background. Ted Haggard was raised in a very religious family with a born-again father and a mother who counted the days to Sunday to help get Ted and his siblings excited about church. Ted remembers dressing in starched shirts and clip-on ties, clipping his nails just before church, and never missing a service. Ted wanted to attend journalism school, but his father pushed him to attend a Christian college. Soon after, Ted recalls receiving a calling from God to become a pastor (Asay, 2007; *Colorado Springs Gazette,* 2002). Even though Ted believes God wanted him to become a pastor, he admits to battling dark sexual desires throughout his adult life, which finally made him behave in inappropriate ways (Haggard, 2006a).

Freud might point to Ted's childhood, which was full of religious pressure, as greatly affecting his personality development and causing problems that eventually overwhelmed Ted. Explaining the complex development of someone's personality, such as Ted Haggard's, is such a difficult task that only a dozen or so psychologists have tried. One of the best-known attempts to explain personality is included in Sigmund Freud's (1901/1960, 1924, 1940) overall theory of psychoanalysis, which includes two related theories: a method of psychotherapy, which we'll discuss in Module 24, and a theory of personality development, which we'll focus on here.

We'll begin with Freud's controversial and revolutionary assumption that unconscious psychological forces influence behavior.

Conscious Versus Unconscious Forces

Why was Ted Haggard fighting his dark side?

Ted Haggard's life was full of inconsistencies. His public behaviors as a pastor and husband were moral and respectable, but his private behaviors of having sexual relations with a male escort were immoral and degrading to his character: "The public person I was wasn't a lie; it was just incomplete . . . the darkness increased and finally dominated me. As a result, I did things that were contrary to everything I believe" (Haggard, 2006a).

Ted indicated that just as he had preached all along, he believed homosexual acts were immoral and lying about a sexual affair was equivalent to "the stinking garbage of a rotting sin" (Haggard, 2006b). In doing so, he was expressing conscious thoughts.

***Conscious thoughts* are wishes, desires, or thoughts that we are aware of, or can recall, at any given moment.**

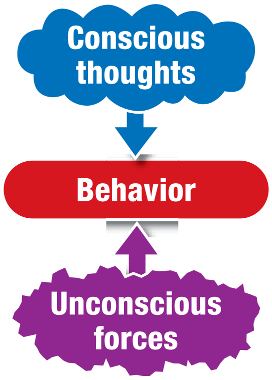
However, Freud theorized that our conscious thoughts are only a small part of our total mental activity, much of which involves unconscious thoughts or forces (Adler, 2006; Westen et al., 2008).

***Unconscious forces* represent wishes, desires, or thoughts that, because of their disturbing or threatening content, we automatically repress and cannot voluntarily access.**

Did Ted have sexual relations with a male escort because of some unconscious forces that he was unaware of and had repressed? According to Freud, although repressed thoughts are unconscious, they may influence our behaviors through unconscious motivation.

***Unconscious motivation* is a Freudian concept that refers to the influence of repressed thoughts, desires, or impulses on our conscious thoughts and behaviors.**

Freud used unconscious forces and motivation to explain why we say or do things that we cannot explain or understand. Once he assumed that there were unconscious forces and motivations, Freud needed to find ways to explore the unconscious.



Freud would say that unconscious thoughts, desires, and feelings influence behaviors.

Techniques to Discover the Unconscious

What was in Ted Haggard's unconscious?

It was one thing for Freud to propose the existence of powerful unconscious psychological forces and motivations, but it was quite another thing for him to show that such unconscious forces actually existed. For example, were there any signs that unconscious psychological forces were making Ted Haggard act out his sexual desires that were contrary to his conscious beliefs?

Ted's very strong religious upbringing and pressure from his father to attend a Christian college may have been too much for Ted to cope with as he was growing up. These early experiences may have served as unconscious forces that led him to act out against his Christian values, such as by having an affair with a male escort even though he was a married pastor with five children. Also, in contrast to his homosexual desires and his long-term relationship with a male escort is his strong public advocacy to ban gay marriages. The inconsistency between the values Ted learned while growing up and his sexual desires during adulthood undeniably led to Ted feeling anxious and guilty. As a way of coping with his anxiety and guilt, Ted actively condemned gay marriages, a behavior that is directly opposite to his own unacceptable thoughts and wishes.

Freud proposed ways to unlock unconscious wishes and feelings.

Because neither Ted nor any of us can easily or voluntarily reveal or talk about our unconscious thoughts and desires, Freud needed to find ways for his patients to reveal their unconscious thoughts and desires, some of which may be psychologically threatening or disturbing. From observing his patients during therapy, Freud believed he had found three techniques that uncovered, revealed, or hinted at a person's unconscious wishes and desires.

Three techniques. Freud's three techniques to uncover the unconscious were free association, dream interpretation, and analysis of slips of the tongue (commonly known as Freudian slips) (Grunbaum, 2006).

Free Association

One of Freud's techniques for revealing the unconscious was to encourage his patients to relax and to sit back or lie down on his now-famous couch and talk freely about anything. He called this process free association.

Free association is a Freudian technique in which clients are encouraged to talk about any thoughts or images that enter their head; the assumption is that this kind of free-flowing, uncensored talking will provide clues to unconscious material.

Free association, which is one of Freud's important discoveries, continues to be used today by some therapists (Lothane, 2006b). However, not all therapists agree that free associations actually reveal a client's unconscious thoughts, desires, and wishes (Grunbaum, 1993).

Dream Interpretation

Freud listened to and interpreted his patients' dreams because he believed that dreams represent the purest form of free association and a path to the unconscious.

Exploring the unconscious with free association, dreams, and slips of the tongue

Dream interpretation, a Freudian technique of analyzing dreams, is based on the assumption that dreams contain underlying, hidden meanings and symbols that provide clues to unconscious thoughts and desires. Freud distinguished between the dream's obvious story or plot, called manifest content, and the dream's hidden or disguised meanings or symbols, called latent content.

For example, Freud interpreted the hidden meaning of dreams' objects such as sticks and knives as being symbols for male sexual organs and interpreted other objects (such as boxes and ovens) as symbols for female sexual organs. The therapist's task is to look behind the dream's manifest content (bizarre stories and symbols) and interpret the symbols' hidden or latent content, which provides clues to a person's unconscious wishes, feelings, and thoughts (Lothane, 2006a).

Freudian Slips

At one time or another, most of us, according to Freud, unintentionally reveal some unconscious thought or desire by making what is now called a Freudian slip (Grunbaum, 2006).

Freudian slips are mistakes or slips of the tongue that we make in everyday speech; such mistakes, which are often embarrassing, are thought to reflect unconscious thoughts or wishes.

For example, a colleague was lecturing on the importance of regular health care. She said, "It is important to visit a veterinarian for regular checkups." According to Freud, mistakes like substituting *veterinarian* for *physician* are not accidental but rather "intentional" ways of expressing unconscious desires. As it turns out, our colleague, who is in very good health, was having serious doubts about her relationship with a person who happened to be a veterinarian.

Freud assumed that free association, dream interpretation, and slips of the tongue share one thing in common: They are all mental processes that are the least controlled by our conscious, rational, and logical minds. As a result, he believed that these three techniques allowed uncensored clues to slip out and reveal our deeper unconscious wishes and desires (Grunbaum, 2006).

According to Freud's theory, there is a continuing battle going on in our minds between conscious thoughts and unconscious forces. How our minds fight these battles is perhaps one of Freud's best-known theories, and you'll easily recognize many of the terms, including id, ego, and superego.

B. Divisions of the Mind

Id, Ego, and Superego

What was in his apology letter?

Ted Haggard wrote an apology letter that was read to his congregation. Ted's letter revealed some of his problems and internal struggle. Here is an excerpt from his letter (Haggard, 2006a): "For extended periods of time, I would enjoy victory and rejoice in freedom. Then, from time to time, the dirt that I thought was gone would resurface, and I would find myself thinking thoughts and experiencing desires that were contrary to everything I believe and teach."

The above excerpt and other quotes you've read earlier in this module suggest Ted was fighting a number of psychological and emotional battles. After years of maintaining his privacy, Ted's problems became public when he confirmed that accusations of him having sexual relations with a male escort were true. According to Freud's theory, some of Ted's driving forces were rising from unconscious battles among three separate mental processes, which you know as the id, ego, and superego.

Freud might say that Haggard's immoral acts result from inner conflicts between his id and superego.

Iceberg example. To understand how the id, ego, and superego interact, imagine an iceberg floating in the sea. The part of the iceberg that is above water represents conscious forces of which we are aware, while parts below the water indicate unconscious forces of which we are not aware.

Freud divided the mind into three separate processes, each with a different function. Because of their different functions, Freud believed that interactions among the id, ego, and superego would result in conflicts (Westen et al., 2008).

Please begin at the top left with number **1**, the id.

1 Id: Pleasure Seeker

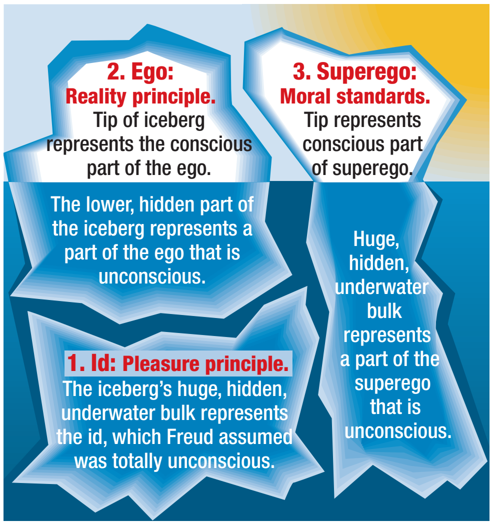
Freud believed that mental processes must have a source of energy, which he called the id.

The ***id,*** which is Freud's first division of the mind to develop, contains two biological drives—sex and aggression—that are the source of all psychic or mental energy; the id's goal is to pursue pleasure and satisfy the biological drives.

Freud assumed that the id operated at a totally unconscious level, which is analogous to an iceberg's massive underwater bulk. The id operates according to the pleasure principle.

The ***pleasure principle*** operates to satisfy drives and avoid pain, without concern for moral restrictions or society's regulations.

You can think of the id as a spoiled child who operates in a totally selfish, pleasure-seeking way without regard for reason, logic, or morality. Simply following the pleasure principle leads to conflict with others (parents), and this conflict results in the development of the ego.



2. Ego:
Reality principle.
Tip of iceberg represents the conscious part of the ego.
3. Superego:
Moral standards.
Tip represents conscious part of superego.
The lower, hidden part of the iceberg represents a part of the ego that is unconscious.
Huge, hidden, underwater bulk represents a part of the superego that is unconscious.
1. Id: Pleasure principle.
The iceberg's huge, hidden, underwater bulk represents the id, which Freud assumed was totally unconscious.

2 Ego: Executive Negotiator between Id and Superego

As infants discover that parents put restrictions on satisfying their wishes, infants learn to control their wishes through the development of an ego.

The ***ego,*** which is Freud's second division of the mind, develops from the id during infancy; the ego's goal is to find safe and socially acceptable ways of satisfying the id's desires and to negotiate between the id's wants and the superego's prohibitions.

Freud said that a relatively large part of the ego's material is conscious (iceberg above water), such as information that we have gathered in adapting to our environments. A smaller part of the ego's material is unconscious (below water), such as threatening wishes that have been repressed. In contrast to the id's pleasure principle, the ego follows the reality principle.

The ***reality principle*** is a policy of satisfying a wish or desire only if there is a socially acceptable outlet available.

You can think of the ego as an executive negotiator that operates in a reasonable, logical, and socially acceptable way in finding outlets for satisfaction. The ego works to resolve conflicts that may arise because of different goals of the id and superego.

3 Superego: Regulator

As children learn that they must follow rules and regulations in satisfying their wishes, they develop a superego.

The ***superego,*** which is Freud's third division of the mind, develops from the ego during early childhood; the superego's goal is to apply the moral values and standards of one's parents or caregivers and society in satisfying one's wishes.

Think of the iceberg's visible tip as representing that part of the superego's moral standards of which we are conscious or aware and the huge underwater bulk as representing the part of the superego's moral standards that are unconscious or outside our awareness.

A child develops a superego through interactions with the parents or caregivers and by taking on or incorporating the parents' or caregivers' standards, values, and rules. The superego's power is in making the person feel guilty if the rules are disobeyed. Because the pleasure-seeking id wants to avoid feeling guilty, it is motivated to listen to the superego. You can think of a superego as a moral guardian or conscience that is trying to regulate or control the id's wishes and impulses.

Disagreements. Freud believed that in some situations there is little or no disagreement between the goals of the id and superego, which means a person experiences little if any conflict. However, in other situations, there could be disagreements between the goals of the id and superego, which result in the ego (executive negotiator) trying to mediate this conflict. Freud describes a number of mental processes that the ego uses to mediate conflicts between the id and superego. We'll next discuss these mental processes, called defense mechanisms.

Photo Credit: © Kevin Moloney/Getty Images

Anxiety

Why do you feel anxious?

Suppose you know that you should study for tomorrow's exam but at the same time you want to go to a friend's party. Freud explained that in this kind of situation there is a conflict between the desires of the pleasure-seeking id and the goals of the conscience-regulating superego, and this conflict causes anxiety.

Anxiety, in Freudian theory, is an uncomfortable feeling that results from inner conflicts between the primitive desires of the id and the moral goals of the superego.

For example, the study-or-party situation sets up a conflict between the pleasure-seeking goal of the id, which is to go to the party, and the conscience-keeping goal of the superego, which is to stay home and study. Caught in the middle of this id–superego conflict is the ego, which, like any good executive, tries to negotiate an acceptable solution. However, this id–superego conflict along with the ego's continuing negotiations to resolve this conflict causes anxious feelings. Freud suggested that the ego, as executive negotiator, tries to reduce the anxious feelings by using a number of mental processes, which he called defense mechanisms (Cramer, 2006).

What happens if you want to party but know you should study?

Defense Mechanisms

Have you ever rationalized?

In trying to decide whether to go to a friend's party or stay home and study for an important exam, a student would experience increasing levels of anxiety. Freud reasoned that anxiety is a sure sign of the id–superego inner conflict and that in order to reduce levels of anxiety, the ego may use defense mechanisms (Cramer, 2003, 2006).

Defense mechanisms are Freudian processes that operate at unconscious levels and that use self-deception or untrue explanations to protect the ego from being overwhelmed by anxiety.

According to Freud, a student's ego has two ways to reduce anxiety over deciding whether to party or study. The student's ego can take realistic steps to reduce anxiety, such as motivating or convincing the student to stay home and study. Or the student's ego can use a number of defense mechanisms, which reduce anxiety by deceiving the student to think it's fine to party and then study tomorrow. Here is a brief summary of some of Freud's more popular defense mechanisms.

Rationalization involves covering up the true reasons for actions, thoughts, or feelings by making up excuses and incorrect explanations.

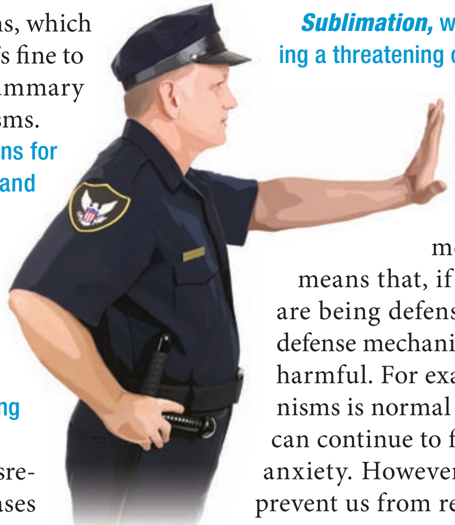
A student may rationalize that by going to a party tonight he or she will feel more motivated to study for the exam tomorrow, even if he or she will be very tired and in no mood or condition to study tomorrow.

Denial is refusing to recognize some anxiety-provoking event or piece of information that is clear to others.

Heavy smokers would be using denial if they disregarded the scientific evidence that smoking increases the risk of lung cancer and cardiovascular disease and in addition would be using rationalization if they say they can quit any time they want.

Repression involves blocking and pushing unacceptable or threatening feelings, wishes, or experiences into the unconscious.

Having feelings of jealousy about your best friend's academic success might be threatening to your self-concept, so you unknowingly block these unwanted feelings by also unknowingly pushing them into your unconscious.



Defense mechanisms function like a mental traffic cop trying to reduce conflict and anxiety.

Projection falsely and unconsciously attributes your own unacceptable feelings, traits, or thoughts to individuals or objects.

A student who refuses to accept responsibility for cheating during exams may look at other students and decide that they are cheating.

Reaction formation involves substituting behaviors, thoughts, or feelings that are the direct opposite of unacceptable ones.

A person who feels guilty about engaging in sexual activity may use reaction formation by joining a religious group that bans sex.

Displacement involves transferring feelings about, or response to, an object that causes anxiety to another person or object that is less threatening.

If you were anxious about getting angry at your best friend, you might unknowingly displace your anger by picking an argument with a safer individual, such as a salesclerk, waiter, or stranger.

Sublimation, which is a type of displacement, involves redirecting a threatening or forbidden desire, usually sexual, into a socially acceptable one.

For instance, a person might sublimate strong sexual desires by channeling that energy into physical activities.

Conclusions. Freud believed defense mechanisms are totally unconscious, which means that, if a best friend or spouse points out that you are being defensive, you will absolutely deny it. We all use defense mechanisms at some time, and they can be helpful or harmful. For example, the occasional use of defense mechanisms is normal and helps reduce conflict and anxiety so we can continue to function as we work on the real cause of our anxiety. However, the overuse of defense mechanisms may prevent us from recognizing or working on the real causes of our anxiety. There is growing scientific evidence that we do indeed use unconscious defense mechanisms much as Freud theorized, which is to reduce anxiety and conflict. In fact, many of us have a dominant or most-often-used defense mechanism, which may be effective in reducing short-term but not necessarily long-term anxiety (M.C. Anderson, 2009d; Cramer, 2003, 2006).

We have discussed the three divisions of the mind—id, ego, and superego—and how the ego may use defense mechanisms to reduce anxiety. Now we'll turn to how one's ego and personality develop.

C. Developmental Stages

Development: Dealing with Conflicts

What shaped Ted's personality?

Imagine a theory so broad that it is able to describe almost exactly how and why your personality developed the way it did and why you did or did not develop certain personality problems along the way. Such is Sigmund Freud's personality theory, which can give a complex description of how each of us develops a different personality.

Case study. For example, let's return to the case of Ted Haggard. He was raised in a strong Christian family that never missed a Sunday service, and his father encouraged him to attend a Christian college. He got married and had five children while becoming the founder of the largest church in Colorado. Ted's life also had a dark side consisting of infidelity, lies, and hypocrisy, all of which made him feel anxious and guilty. He preached one thing and did the opposite behind everyone's back. When his immoral acts were discovered, he confessed to church officials but then went on a television news broadcast smiling happily and denying all accusations.

Psychosexual stages. According to Freud, the development of Ted's personality, such as being all smiles on the outside but feeling anxious and guilty internally, was primarily influenced by how he dealt with the five different kinds of conflicts that occurred at five different times or stages. According to Freud (1940), our personality develops as we pass through and deal with potential conflicts at five psychosexual stages.

According to Freud, Haggard's personality developed as he passed through five psychosexual stages.

Psychosexual stages are five developmental periods—oral, anal, phallic, latency, and genital stages—each marked by potential conflict between parent and child. The conflicts arise as a child seeks pleasure from different body areas that are associated with sexual feelings (different ***erogenous zones***). Freud emphasized that the child's first five years were most important in personality development.

You can think of each psychosexual stage as being a source of potential ***conflict*** between the child's id, which seeks immediate gratification, and the parents, who place restrictions on when, where, and how the gratification can take place. For example, the child may want to be fed immediately, while the parent may wish to delay the feeding to a more convenient time. The kind of interactions that occur between parent and child in satisfying these psychosexual needs and the way a child learns to deal with psychosexual conflicts, especially during breast feeding or toilet training, will greatly influence the personality development as well as future problems and social interactions.

One of Freud's controversial ideas is the relationship between early psychosexual stages and the development of later personality, social, and emotional problems. Here is Freud's explanation of how different problems may arise.

Fixation: Potential Personality Problems

Why did Ted develop problems?

Freud explained that the way a person deals with early psychosexual conflicts lays the groundwork for personality growth and future problems. This means that, to a large extent, Ted's later personality problems grew out of early childhood experiences. Freud would say that Ted's problems in finding his identity began in childhood, likely as a result of having a specific need or wish that was either undergratified or overgratified.

Fixation. As an adult, there were times when Ted was happy, but at other times he was anxious and guilt-ridden. The problem for any theory of personality is to explain how problems and contradictions in personality occur. For example, why did Ted preach in front of 14,000 worshippers and become politically active, yet engage in immoral sexual conduct and then lie about it? Freud would explain that the development of Ted's personality depended, to a large extent, on the way he dealt with early psychosexual conflicts. One way a child can deal with or resolve these conflicts—wanting to satisfy all desires but not being allowed to by the parents—is to become fixated at a certain stage.

Healthy personality involves resolving conflicts during the psychosexual stages.

Fixation, which can occur during any of the first three stages—oral, anal, or phallic—refers to a Freudian process through which an individual may be locked into a particular psychosexual stage because his or her wishes were either overgratified or undergratified.

For example, if a person were fixated at the oral stage because of ***too little*** gratification, he might go through life trying to obtain oral satisfaction through eating too much, boasting too much, or focusing on other oral behaviors. If fixation had occurred at the oral stage because of ***too much*** gratification, he might focus on seeking oral gratification while neglecting to develop other aspects of his personality.

Next, we'll summarize Freud's psychosexual stages, focusing on possible parent–child conflicts, problems from fixation, and implications for future personality and social development.

Fixation at one psychosexual stage can cause sexual problems.

Five Psychosexual Stages

What happens during the stages?

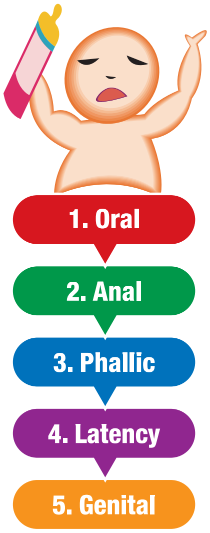
According to Freud, every child goes through certain situations, such as nursing, bottle feeding, and toilet training, that contain potential conflicts between the child's desire for instant satisfaction or gratification and the parents' wishes, which may involve delaying the child's satisfaction. How these conflicts are resolved and whether a child becomes fixated at one stage because of too much or too little satisfaction greatly influence the development of personality and onset of future problems.

1 Oral Stage

Time. Early infancy: first 18 months of life.

Potential conflict. The ***oral stage*** lasts for the first 18 months of life and is a time when the infant's pleasure seeking is centered on the mouth.

Pleasure-seeking activities include sucking, chewing, and biting. If we were locked into or fixated at this stage because our oral wishes were gratified too much or too little, we would continue to seek oral gratification as adults. ***Fixation*** at this stage results in adults who continue to engage in oral activities, such as overeating, gum chewing, or smoking; oral activities can be symbolic as well, such as being overly demanding or "mouthing off."



2 Anal Stage

Time. Late infancy: 1½ to 3 years.

Potential conflict. The ***anal stage*** lasts from the age of about 1½ to 3 years and is a time when the infant's pleasure seeking is centered on the anus and its functions of elimination.

Fixation at this stage results in adults who continue to engage in activities of retention or elimination. Retention may take the form of being very neat, stingy, or behaviorally rigid (thus the term *anal retentive*). Elimination may take the form of being generous, messy, or very loose or carefree (thus the term *anal expulsive*).

Freud would say that Ted's personality depended to a large extent on what happened during five psychosexual stages.

3 Phallic Stage

Time. Early childhood: 3 to 6 years.

Potential conflict. The ***phallic** (FAL-ick)* ***stage*** lasts from the age of about 3 to 6 and is a time when the infant's pleasure seeking is centered on the genitals.

Freud theorized that the phallic stage is particularly important for personality development because of the occurrence of the Oedipus complex (named for Oedipus, the character in Greek mythology who unknowingly killed his father and married his mother).

The ***Oedipus** (ED-ah-pus)* ***complex*** is a process in which a child competes with the parent of the same sex for the affections and pleasures of the parent of the opposite sex.

According to Freud, the Oedipus complex causes different problems for boys and girls.

Boys. When a boy discovers that his penis is a source of pleasure, he develops a sexual attraction to his mother. As a result, the boy feels hatred, jealousy, and competition toward his father and has fears of castration. The boy resolves his Oedipus complex by identifying with his father. If he does not resolve the complex, fixation occurs and he may go through life trying to prove his toughness.

Girls. When a girl discovers that she does not have a penis, she feels a loss that Freud called ***penis envy.*** Her loss makes her turn against her mother and develop sexual desires for her father. A girl resolves her Oedipus complex, sometimes called the Electra complex (for Electra, a woman in Greek mythology who killed her mother), by identifying with her mother. If this complex is not resolved, fixation occurs and the woman may go through life feeling inferior to men.

Over the years, the idea of the Oedipus complex has waned in popularity and credibility, both within psychoanalysis and within the culture at large. That's because there are significant challenges in scientifically testing this idea. Still, scientific studies do show some support for the existence of the Oedipus complex (Westen et al., 2008).

4 Latency Stage

Time. Middle and late childhood: 6 to puberty.

Potential conflict. The ***latency stage,*** which lasts from about age 6 to puberty, is a time when the child represses sexual thoughts and engages in nonsexual activities, such as developing social and intellectual skills.

At puberty, sexuality reappears and marks the beginning of a new stage, called the genital stage.

5 Genital Stage

Time. Puberty through adulthood.

Potential conflict. The ***genital stage*** lasts from puberty through adulthood and is a time when the individual has renewed sexual desires that he or she seeks to fulfill through relationships with other people.

How a person meets the conflicts of the genital stage depends on how conflicts in the first three stages were resolved. If the individual is fixated at an earlier stage, less energy will be available to resolve conflicts at the genital stage. If the individual successfully resolved conflicts in the first three stages, he or she will have the energy to develop loving relationships and a healthy and mature personality.

Summary. Freud's psychodynamic theory of personality development made a number of assumptions that, at the time, were revolutionary. His assumptions included the influence of unconscious forces; the division of the mind into the id, ego, and superego; the importance of resolving conflicts at five psychosexual stages; the importance of fixation; and the importance of the first five years to personality development.

Next, we'll discuss what Freud's critics have had to say about his theory and assumptions.

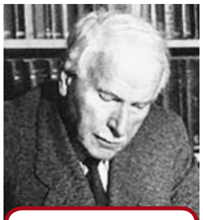
D. Freud's Followers & Critics

Disagreements

What did they argue about?

Because Freud's theory was so creative and revolutionary for its time, it attracted many followers, who formed a famous group called the Vienna Psychoanalytic Society. However, it was not long before members of the society began to disagree over some of Freud's theories and assumptions, such as whether Freud placed too much emphasis on biological urges (sex and aggression), psychosexual stages, and importance of early childhood experience in personality development (Horgan, 1996; Westen et al., 2008). We'll focus on three influential followers who broke with Freud's theory.

Carl Jung



Jung disagreed on the importance of the sex drive.

Why did Freud's "crown prince" stop talking to him? In 1910 Carl Jung, with the wholehearted support of Sigmund Freud, became the first president of the Vienna Psychoanalytic Society. Freud said that Jung was to be his "crown prince" and personal successor. However, just four years later, Jung and Freud ended their personal and professional relationship and never again spoke to each other.

The main reason for the split was that Jung disagreed with Freud's emphasis on the sex drive. Jung believed the collective unconscious—and not sex—was the basic force in the development of personality.

The ***collective unconscious,*** according to Jung, consists of ancient memory traces and symbols that are passed on by birth and are shared by all peoples in all cultures.

Jung's theory of collective unconscious and his elaborate theory of personality, called ***analytical psychology,*** had more influence on the areas of art, literature, philosophy, and counseling/therapy than on current areas of psychology.

Alfred Adler

Adler disagreed on the importance of biological urges.

Why did one of the society's presidents resign? Alfred Adler was another contemporary of Freud's who later became president of the Vienna Psychoanalytic Society. However, after Adler voiced his disagreement with Freud at one of the society's meetings, he was so badly criticized by the other members that he resigned as president.

Like Jung, Adler disagreed with Freud's theory that humans are governed by biological and sexual urges. Adler believed that the main factors influencing a child's development were sibling influences and child-rearing practices.

In contrast to Freud's biological drives, Adler proposed that humans are motivated by ***social urges*** and that each person is a social being with a unique personality. Adler formed his own group, whose philosophy became known as ***individual psychology.*** In contrast to Freud's emphasis on unconscious forces that influence our behaviors, Adler suggested that we are aware of our motives and goals and have the capacity to guide and plan our futures.

Karen Horney

Horney disagreed on the importance of penis envy.

What would a woman say about penis envy? Karen Horney was trained as a psychoanalyst; her career reached its peak shortly after Freud's death in 1939. For many years, Horney was dean of the American Institute of Psychoanalysis in New York.

Horney strongly objected to Freud's view that women were dependent, vain, and submissive because of biological forces and childhood sexual experiences. She especially took issue with Freud's idea that penis envy affects girls' development.

In contrast to Freud's psychosexual conflicts, Horney insisted that the major influence on personality development, whether in women or men, can be found in child–parent ***social interactions.*** Unlike Freud, who believed that every child must experience child–parent conflicts, Horney theorized that such conflicts are avoidable if the child is raised in a loving, trusting, and secure environment. Karen Horney would now be called a feminist and is credited with founding the psychology of women.

Neo-Freudians

Neo-Freudians focused on social and cultural factors.

Karen Horney is sometimes referred to as a ***neo-Freudian*** because she changed and renovated Freud's original theory. One of the best-known neo-Freudians was Erik Erikson, who formulated his own theory of personality development, which we discussed in Modules 17 and 18. Erikson proposed that everyone goes through a series of ***psychosocial*** stages, rather than the ***psychosexual*** stages proposed by Freud.

Neo-Freudians generally agreed with Freud's basic ideas, such as the importance of the unconscious; the division of the mind into the id, ego, and superego; and the use of defense mechanisms to protect the ego. However, they mostly disagreed with Freud's placing so much emphasis on biological forces, sexual drives, and psychosexual stages. The neo-Freudians turned the emphasis of Freud's psychodynamic theory away from biological drives toward psychosocial and cultural influences (Plante, 2005).

From early on, followers of Freud criticized his theory and, as you'll see, criticisms continue to the present day.

Module 11
D. Long-Term Memory: Storing

Freudian Theory Today

What is the current status of Freud's theory?

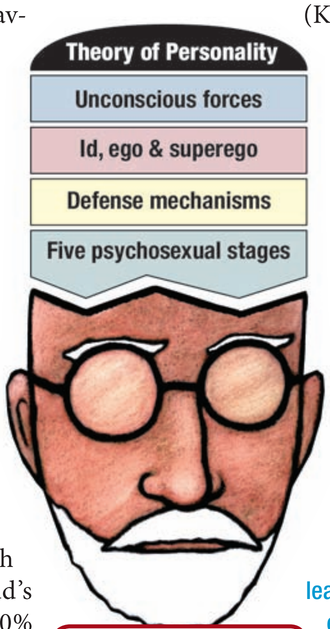
In 1993, *Time* magazine's cover featured a picture of Sigmund Freud with the question "Is Freud Dead?" Answering this question with a loud "Yes" are several scholarly books that seriously question Freud's theory and all its assumptions (Crews, 1996, 1999). Answering this question with a loud "No" are hundreds of members of the American Psychological Association's psychoanalysis division and many neuroscientists who meet the attacks on Freud with equally strong defenses (Horgan, 1996; Solms, 2006). To give you an idea of where Freud's theory stands today, we'll focus on four questions: How valid is Freud's theory? How important are the first five years? Are there unconscious forces? What was the impact of Freud's theory?

1 How Valid Is Freud's Theory?

Too comprehensive. Freud's psychodynamic theory, which includes how the mind develops (id, ego, and superego), how personality develops (psychosexual stages), and how to do therapy (psychoanalysis), is so comprehensive that it can explain almost any behavior. Advocates of Freud's theory state that it is a coherent and sophisticated view of the mind, while critics argue that Freud's theory is too comprehensive to be useful in explaining or predicting behaviors (Horgan, 1996; Kandel, 2006).

Difficult to test. Current followers agree that some of Freud's concepts, such as the id being the source of energy, the importance of the Oedipus complex in personality development, and basic drives limited to sex and aggression, have been difficult to test or verify. The same followers add that other Freudian ideas, such as the influence of unconscious forces, the long-term effects of early childhood patterns, and the existence of defense mechanisms, have been experimentally tested and received support (Fotopoulou, 2006; Ramachandran, 2006; Westen et al., 2008).

Must be updated. However, if psychoanalysis or psychodynamic theory is to survive in the 2000s, Freud's theory must continue to be tested experimentally and updated with findings from other areas of psychology. For example, Freud's theory needs to include how ***genetic factors*** account for 20% to 50% of a wide range of behaviors and explain how ***brain development,*** which is not complete until early adulthood, is associated with and necessary for the development of related behaviors, thoughts, and feelings (Westen, 1998). Currently, neuroscientists are examining many of Freud's questions about the mind and hope to build upon his theory (Solms, 2006).



During the 1990s, Freud's theory had several major revisions.

2 How Important Are the First Five Years?

Based on observations of his patients, Freud concluded that personality development is essentially complete after the first five years. However, Freud never did systematic research or collected longitudinal observations to support his hypothesis that personality development is fixed during a child's first five years (Bruer, 1999). In fact, there are two lines of research showing the opposite. First, our earlier discussion of ***resilient children*** (p. 394) indicated that the occurrence of serious psychological and physical problems during the first five years does not necessarily stunt or inhibit personality development, as Freud predicted.

Second, a number of ***longitudinal studies*** that followed children into adulthood indicate that personality development is not complete in the first five years but rather continues well into middle adulthood (Caspi & Roberts, 1999; R. R. McCrae & Costa, 2003). For these reasons, current psychologists question Freud's idea that personality development is complete in the first five years.

3 Are There Unconscious Forces?

One of Freud's major assumptions was that unconscious or repressed forces influence our conscious thoughts and behaviors. An esteemed scientist says 80–90% of what we do is unconscious (Kandel, 2008). For instance, when you speak, you use correct grammar while paying little or no conscious attention to doing so. Patterns of brain activity can actually reveal which choice a person is going to make before he or she is aware of it. In one study, researchers took brain scans of people while they held a button in each hand and were instructed to push either button. The brain scans revealed which hand people were going to use before the people were even aware they had made a decision (Haynes, 2008).

In contrast to Freud's theory of the repressed unconscious forces, cognitive neuroscientists developed a different concept, called implicit or nondeclarative memory (p. 246) (Solms, 2006).

Implicit or ***nondeclarative memory*** means learning without awareness, such as occurs in experiencing emotional situations or acquiring motor habits. Although we are unaware of such learning, it can influence our conscious feelings, thoughts, and behaviors.

Thus, there is strong evidence for the ***influence of unconscious forces*** on conscious thoughts, feelings, and behaviors (Bargh & Morsella, 2008).

4 What Was Freud's Impact?

Freud's theory has had an enormous impact on society, as can be seen in the widespread use of Freudian terms (*ego, id, rationalization*) in literature, art, and our everyday conversations. Freud's theory also has had a great impact on psychology: Many of his concepts have been incorporated into the fields of personality, development, abnormal psychology, and psychotherapy. For example, researchers found that repeatedly exposing people who have spider phobias to spider-related images at a subliminal level (below awareness) improves their ability to approach spiders (J. Weinberger et al., 2008). However, as we discussed, some of Freud's ideas are difficult to verify (Oedipus complex), and Freud's psychoanalytic theory was modified in the 1990s (Guterl, 2002; Westen et al., 2008).

Unlike Freud's psychodynamic theory, which paints a picture of humans filled with irrational and unconscious forces with little free choice, we next discuss a family of theories—humanistic theory—that is almost the direct opposite of Freud's theory.

E. Humanistic Theories

How did he develop his real potential?

At the beginning of this module, we told you about two very different people. One was evangelical Christian leader Ted Haggard, who struggled with numerous personal problems. At age 50, as a husband, father, and national evangelical leader, he confessed to having sexual relations with a male escort and purchasing drugs.

The other person was Charles Dutton, who had been in and out of reform schools since he was 12 years old, was sent to prison on charges of manslaughter, and spent time in solitary confinement for his ringleader role in a prison riot. Just when most people would have given up on reforming Dutton, he began to reform himself. Inspired by reading a book of plays, he began to channel his rage against society into becoming a student and then an actor. After leaving prison, Charles Dutton (right photo) worked hard to change his life and became a very successful theater, television, and movie actor and director (Brantley, 2003; M. Schneider, 2007).

When most would have given up, Charles Dutton turned his life around.

What Dutton and Haggard shared in common as young men was that neither showed particular evidence of having special talents or great potentials. Few people would have predicted that Ted Haggard, who as a teen wanted to pursue journalism, would become a nationally recognized Christian pastor. No one would have predicted that angry, tough, mean Charles Dutton would discover, of all things, acting and would channel his anger into becoming a very successful professional actor. The lives of these two men demonstrate the difficulty in predicting someone's potential and whether he or she will develop it. Developing our potential is at the heart of humanistic theories.

Humanistic theories **emphasize our capacity for personal growth, development of our potential, and freedom to choose our destiny.**

Humanistic theories reject the biological determinism and the irrational, unconscious forces of Freud's psychodynamic theory. Humanistic theories emphasize freely choosing to go after one's dream and to change one's destiny, as Lorena Ochoa is doing.

Three Characteristics of Humanistic Theories

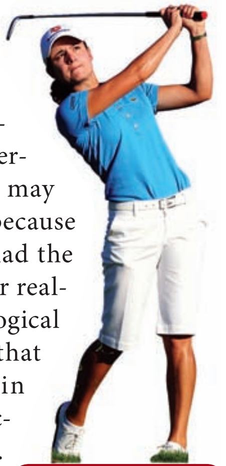
What was her goal?

Lorena Ochoa has always set high goals. Since childhood, she has aimed to become the world's best golfer. Lorena started golfing at the age of 5, and by age 7, she was playing in tournaments. Her countless hours of practicing, training, and pushing herself to the limits helped her to become the top-ranked female golfer in the world. What makes Lorena even more amazing is her humanitarian efforts. She started a foundation to improve education for children in Mexico. Her foundation built an elementary school and will soon build a high school (Kantrowitz, 2007; Lopez, 2008; Ochoa, 2007).

Lorena Ochoa's life illustrates the humanists' emphasis on developing fully one's potential to lead a rich and meaningful life and becoming the best person one can be (Moss, 2002). Lorena's drive to reach her lifelong dream exemplifies the three characteristics that distinguish humanistic theories from other theories of personality. We'll describe each of the three characteristics unique to humanistic theories: a phenomenological perspective, a holistic view, and a goal of self-actualization (P. T. P. Wong, 2006).

1 Humanistic theories stress learning about the world through personal experiences, which illustrates the phenomenological *(feh-nom-in-no-LODGE-uh-cal)* perspective.

The ***phenomenological perspective*** **means that your perception or view of the world, whether or not it is accurate, becomes your reality.**



Lorena's life dream has been to become the world's best golfer.

For instance, Lorena's phenomenological perspective of how she perceived her golfing abilities may or may not have been accurate. However, because she believed so strongly that she had the abilities, this perception became her reality. Other examples of phenomenological perspectives are long-held beliefs that women could not perform certain jobs—for example, police officer, doctor, plumber, truck driver, or lawyer. Since women have demonstrated that they can perform these jobs, this particular perception has been proven false.

2 Humanistic theories emphasize looking at the whole situation or person, which illustrates the holistic *(hole-LIS-tick)* view.

The ***holistic view*** **means that a person's personality is more than the sum of its individual parts; instead, the individual parts form a unique and total entity that functions as a unit.**

For example, the holistic view would explain that Lorena became the top-ranked female golfer in the world because of her unique combination of many traits—discipline, ability, motivation, desire—rather than any single trait.

3 Humanistic theories highlight the idea of developing one's true potential, which is called self-actualization.

Self-actualization **refers to our inherent tendency to develop and reach our true potentials.**

By becoming a professional golfer and humanitarian, Lorena is a wonderful example of someone who is developing and reaching her true potential and thus is getting closer to achieving a high level of self-actualization. According to humanists, each of us has the capacity for self-actualization. Humanists believe that one's self-esteem, self-expression, sense of belonging, creativity, and love are as important to human life as the biological needs of food and water (Rabasca, 2000a).

The beginning of humanistic theories in the 1960s can be traced to two psychologists—Abraham Maslow and Carl Rogers. They had surprisingly different backgrounds but arrived at the same uplifting ideas.

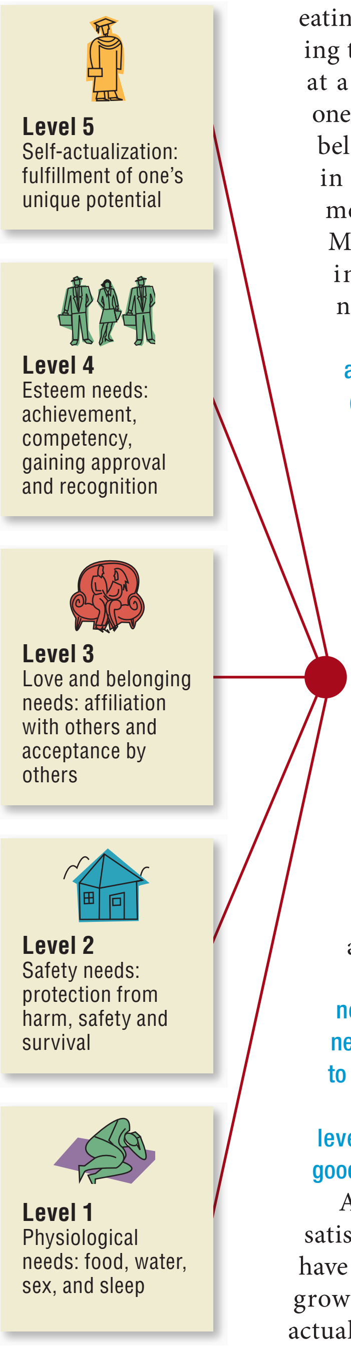
Maslow: Need Hierarchy and Self-Actualization

Why did a behaviorist become a humanist?

We can trace the official beginning of the humanistic movement to the early 1960s and the publication of the *Journal of Humanistic Psychology*. One of the major figures behind establishing this journal was Abraham Maslow. Interestingly enough, Maslow was trained as a behaviorist, but along the way he felt there was too much emphasis on rewards and punishments and observable behaviors and too little emphasis on other important aspects of human nature, such as feelings, emotions, and beliefs. For these reasons, Maslow (1968) broke away from the reward/punishment/observable behavior mentality of behaviorism and developed his humanistic theory, which emphasized two things: our capacity for growth, or self-actualization, and our desire to satisfy a variety of needs, which he arranged in a hierarchy.

Maslow's Hierarchy of Needs

Maslow's Hierarchy of Needs



Level 5
Self-actualization: fulfillment of one's unique potential
Level 4
Esteem needs: achievement, competency, gaining approval and recognition
Level 3
Love and belonging needs: affiliation with others and acceptance by others
Level 2
Safety needs: protection from harm, safety and survival
Level 1
Physiological needs: food, water, sex, and sleep

For just a moment, think of all the needs that you try to meet each day: eating, having a safe place to live, talking to your friends, perhaps working at a part-time job, caring for loved ones, and studying for exams. Maslow believed that you satisfy these needs in a certain order. As you may remember from Module 15 (p. 333), Maslow arranged all human needs into a hierarchy of five major needs.

Maslow's hierarchy of needs **arranges needs in ascending order (figure on left), with biological needs at the bottom and social and personal needs at the top. Only when needs at a lower level are met can we advance to the next level.**

According to Maslow's hierarchy, you must satisfy your biological and safety needs before using energy to fulfill your personal and social needs. Finally, you can devote time and energy to reaching your true potential, which is called self-actualization, your highest need.

Maslow divided our needs into two general categories: deficiency and growth needs.

Deficiency needs **are physiological needs (food, sleep) and psychological needs (safety, love, esteem) that we try to fulfill if they are not met.**

Growth needs **are those at the higher levels and include the desire for truth, goodness, beauty, and justice.**

According to Maslow, we must satisfy our deficiency needs before we have the time and energy to satisfy our growth needs and move toward self-actualization.

Self-Actualization

One of the major characteristics of the humanistic movement is the emphasis on a process called self-actualization.

Self-actualization **refers to the development and fulfillment of one's unique human potential.**

Maslow (1971) developed the concept of self-actualization after studying the lives of highly productive and exceptional people, such as Abraham Lincoln, Albert Einstein, and Eleanor Roosevelt. Maslow believed that these individuals had been able to reach the goal of self-actualization because they had developed the following personality characteristics.

Characteristics of Self-Actualized Individuals

- They perceive reality accurately.
- They are independent and autonomous.
- They prefer to have a deep, loving relationship with only a few people.
- They focus on accomplishing their goals.
- They report peak experiences, which are moments of great joy and satisfaction.

Maslow believed that, although very few individuals reach the level of self-actualization, everyone has a self-actualizing tendency. This tendency motivates us to become the best kind of person we are capable of being.

There is no doubt that Maslow would also have considered Martin Luther King, Jr., an example of a self-actualized person. Martin Luther King, Jr., devoted his life to achieving civil rights for all people. At left he delivers his famous "I Have a Dream" speech at a civil rights rally in Washington, D.C. He was awarded the Nobel Prize for peace at age 35. He was gunned down by an assassin's bullet at age 39. King's achievements exemplify the humanistic idea of self-actualization.

Civil rights leader Martin Luther King, Jr., is an example of a self-actualized person.

About the same time that Maslow was making this journey from behaviorism to humanism and developing the concept of self-actualization, another psychologist by the name of Carl Rogers was developing a different but related humanistic theory.

E. Humanistic Theories

Rogers: Self Theory

What are the two most important concepts?

Carl Rogers was initially trained in the psychodynamic approach, which he used in his practice as a clinical psychologist. However, Rogers began to feel that Freud placed too much emphasis on unconscious, irrational forces and on biological urges, and too little emphasis on human potential for psychological growth. As a result, Rogers gradually abandoned the psychodynamic approach in favor of a new theory of personality that he developed in the 1960s. Rogers's new humanistic theory is often called self theory because of his emphasis on the self or self-concept.

Because of different experiences, the boy in the wheelchair will likely develop a different concept of self than the other boy.

Self theory, also called ***self-actualization theory,*** is based on two major assumptions: that personality development is guided by each person's unique self-actualization tendency, and that each of us has a personal need for positive regard.

Rogers's first major assumption about self-actualization is similar but slightly different from Maslow's use of the term.

Rogers's ***self-actualizing tendency*** refers to an inborn tendency for us to develop all of our capacities in ways that best maintain and benefit our lives.

The self-actualizing tendency relates to ***biological functions,*** such as meeting our basic needs for food, water, and oxygen, as well as ***psychological functions,*** such as expanding our experiences, encouraging personal growth, and becoming self-sufficient.

The self-actualizing tendency guides us toward positive or healthful behaviors rather than negative or harmful ones. For example, one of the two boys in the photo below has lost the use of his legs and must use a wheelchair. Part of his self-actualizing process will include learning to deal with his disability, engaging in positive healthful behaviors, and getting to know himself.

Self or ***self-concept*** refers to how we see or describe ourselves. The self is made up of many self-perceptions, abilities, personality characteristics, and behaviors that are organized and consistent with one another.

Because of very different experiences, the boy in the wheelchair will develop a self-concept different from that of his friend who has normal use of his legs. According to Rogers (1980), self-concept plays an important role in personality because it influences our behaviors, feelings, and thoughts. For example, if you have a ***positive self-concept,*** you will tend to act, feel, and think optimistically and constructively; if you have a ***negative self-concept,*** you will tend to act, feel, and think pessimistically and destructively.

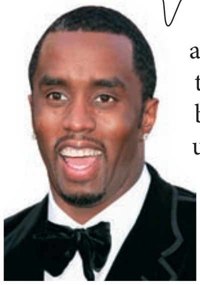
Sometimes a person may be undecided about his or her real self. As we discover our real self, we may undergo a number of changes in personality.

Real Self Versus Ideal Self

Who is the real Sean Combs?

We all change how we see ourselves but probably not as much as hip-hop star Sean Combs, who, through the years, has radically changed his appearance and even his name. For example, at the start of his career, Combs was known as "Puff Daddy" and his appearance (top photo) and behaviors (legal problems) might have been described as pushing some of society's limits. Now, however, Combs is known as "Diddy" and has a rather conventional appearance (bottom photo). He has donated huge amounts to charities, and he previously attempted to release a gospel album, unlike his other albums that all require a "Parental Advisory" warning. The question is: Which is Combs's real self?

My ideal self is based on my hopes and wishes.



My real self is based on my actual experience.

Carl Rogers said that his clients often asked questions related to their selves: "How do I find myself?" "Why do I sometimes feel that I don't know myself?" "Why do I say or do things that aren't really me?" Rogers developed a clever answer to these relatively common and perplexing questions. He said there are two kinds of selves: a real self and an ideal self.

The ***real self,*** according to Rogers, is based on our actual experiences and represents how we really see ourselves.

The ***ideal self,*** according to Rogers, is based on our hopes and wishes and reflects how we would like to see ourselves.

In some cases, the hopes and wishes of one's ideal self may contradict the abilities and experiences of the real self. For example, a student's ideal self may be someone who is very responsible and studies hard, but the real self may be someone who puts things off and studies less than is required.

Contradiction between ideal and real self. According to Rogers, a glaring contradiction between the ideal and real selves can result in personality problems. Rogers suggested that we can resolve contradictions between our ideal and real selves by paying more attention to our actual experiences, working to have more positive experiences, and paying less attention to the expectations of others. In working out discrepancies between our ideal and real selves, we may undergo a variety of changes in our appearance and behaviors, such as Sean Combs experienced.

Now that you know what the self is, here's how Rogers says that it develops.

Positive Regard

Why are there millions of dog owners?

One reason I (H. K.) am one of the millions of dog owners is that my dog Cocoa shows great happiness at seeing me, no matter how grouchy, distracted, or sad I may feel or act. In fact, researchers find that because people perceive their pets as showing appreciation, being supportive, and giving pleasure, pets are helpful in reducing stressful feelings and lowering blood pressure (K. Allen, 2003; Lilienfeld & Arkowitz, 2008a; Springen, 2008). The healing power of pets can be so strong that patients with heart failure report having less anxiety and stress when visited in the hospital by dogs rather than people (Song, 2005). Some doctors have begun to encourage hospital patients to have their pets visit them (Peters, 2008).

It's so nice you're always glad to see me.

Pets can be especially helpful during times of loneliness, when people need to feel appreciated and loved. As such, pets can be a great source of companionship and social support for people who have depression and children who have been neglected, many of whom feel lonely and lack social support (Lilienfeld & Arkowitz, 2008a).

The need to feel appreciated is so important we have a number of days throughout the year that are designated for appreciation, such as Mother's, Father's, Grandparent's, and Secretary's days, as well as birthdays and the heartfelt Valentine's Day.

The creation of appreciation days and the popularity of pets illustrate the second assumption of Carl Rogers's self theory, which is that we have a need to receive positive regard.

Positive regard **includes love, sympathy, warmth, acceptance, and respect, which we crave from family, friends, and people who are important to us.**

Rogers believed that positive regard was essential for the healthy development of one's self and for successful interpersonal relationships (Liebert & Spiegler, 1994).

Conditional and Unconditional Positive Regard

What's a big problem for teenagers?

Unlike friends and family, pets never pass judgment; they provide endless amounts of positive regard no matter how their owners look, feel, dress, or talk. In contrast, friends and family can be very judgmental and may give only conditional positive regard.

Conditional positive regard **refers to the positive regard we receive if we behave in certain acceptable ways, such as living up to or meeting the standards of others.**

For instance, one way teenagers display their independence is by choosing different (radical, awful, outrageous) hairstyles and fashions. In this case, if the teenagers receive only conditional positive regard based on conforming to the traditional fashion standards of their parents, they may develop a negative self-concept or feel bad or worthless because they displeased or disappointed their parents. Rogers believed the development of a healthy and positive self-concept depends on receiving as much unconditional positive regard as possible.

No matter how she dresses, she hopes to get unconditional positive regard.

Unconditional positive regard **refers to the warmth, acceptance, and love that others show you because you are valued as a human being even though you may disappoint people by behaving in ways that are different from their standards or values or the way they think.**

Parents who provide love and respect, even if a teenager does not always abide by their fashion standards, are showing unconditional positive regard, which will foster the development of a healthy self-concept.

Importance of Self-Actualization

What does it take to reach your potential?

Carrie Underwood was the winner of the fourth season of "American Idol" and has since become a multi-platinum-selling recording artist, winning countless awards and prestigious recognitions. For instance, her debut album, *Some Hearts,* was the fastest-selling female country album ever, and she was voted Female Vocalist of the Year at the 40th Annual Country Music Association Awards in 2006.

The life of Carrie Underwood is a case study in self-actualization. Her dream since childhood was to become a professional singer, and despite years of disappointing attempts to establish a singing career, she never lost sight of her dream. Rogers would explain that Underwood persisted in singing because of the tendency for self-actualization, which provides direction and motivation to develop one's potential.

I never gave up on my dream to be a singer.

Rogers recognized that our tendency for self-actualization may be hindered, tested, or blocked by a variety of situational hurdles or personal difficulties, as happened to Underwood. But like Underwood, Rogers believed that we will experience the greatest self-actualization if we work hard and diligently to remove situational problems, resolve our personal problems, and, hopefully, receive tons of unconditional positive regard.

Humanistic theories contain powerful positive messages, but how do these uplifting messages work in real life?

E. Humanistic Theories

Applying Humanistic Ideas

What problems do at-risk students face?

Unlike almost every other theory of personality, humanism holds that people are basically good and can achieve their true potentials if the roadblocks placed by society, poverty, drugs, or other evil influences are removed (Megargee, 1997). One of the primary goals of the humanistic approach is to find ways of removing blocking influences so people can grow and self-actualize.

In 1998, a racially diverse group of 150 high-school seniors walked across a graduation stage, an event few people expected to ever happen. These teenagers grew up in rough neighborhoods, witnessing and, for many, being victims of gun shootings. At the start of high school, these students made it clear they hated school and had no desire to learn. Thus, they were labeled "unteachable, at-risk" students. So, how did these 150 disadvantaged students overcome the many roadblocks on the path to graduating from high school?

The Freedom Writers shattered stereotypes because of the positive regard received from their teacher, Erin Gruwell.

Helping these students overcome roadblocks was Erin Gruwell, a dedicated teacher and role model. Erin encouraged students to think beyond the negative expectations others had of them and to actively set life goals. By believing in each of her students, Erin helped them develop and reach their own potentials. At the heart of Erin's teaching was providing positive regard, including warmth, acceptance, and respect, to show them that someone truly cares.

With Erin's support, these students shattered stereotypes by not only graduating from high school but also going on to earn undergraduate and graduate degrees. The lives of these students had been transformed and it did not stop at their education. These 150 students are now known as the "Freedom Writers," and their mission is to teach tolerance and inspire others through their success. The Freedom Writers shared their story in the book they wrote together, *The Freedom Writers Diary.* Later, a Hollywood movie was made about their amazing success, *Freedom Writers* (Freedom Writers, 1999; Gruwell, 2007).

In the United States, there are many mentoring programs, such as Big Brothers/Big Sisters of America, that instill a sense of pride and self-confidence and give children the motivation to achieve success. Children who participated in mentoring programs reported significantly higher self-confidence, grades, and social skills than children without mentors (Vredenburgh, 2007). Thus, applying humanistic principles helped improve the self-confidence, grades, and social skills of children who came from problem families or neighborhoods.

Next, we'll review the important humanistic concepts and discuss what critics have to say about humanistic theories.

Evaluation of Humanistic Theories

How popular is humanism?

Perhaps the main reason humanistic theories, such as those of Maslow and Rogers, continue to be popular is that they view people as basically good and believe that people can develop their true potentials (Clay, 2002). However, these optimistic views of human nature have triggered a number of criticisms.

Impact

In the case of the Freedom Writers described above, the sense of self-worth of at-risk students skyrocketed when their teacher and successful role model, Erin Gruwell, provided lots of positive regard. This program illustrates the humanistic theories' emphasis on building self-worth through positive regard. In a real sense, Erin Gruwell removed roadblocks so that students could find a path to their true potential through a process called self-actualization (K. J. Schneider et al., 2002).

Humanistic theories have had their greatest impact in counseling, clinical settings, and personal growth programs, where ideas like self-concept, self-actualization, and self-fulfillment have proven useful in developing healthy personalities and interpersonal relationships (Rabasca, 2000a; Soyez & Broekaert, 2005). Compared to Freud's idea that we are driven by unconscious irrational forces, humanism says we are driven by positive forces that point us toward realizing our good and true selves.

Criticisms

Humanistic theories have come under considerable criticism because Rogers and Maslow provided little or no scientific evidence that an inherent (biological) tendency to self-actualization really exists. Because the major assumption of self-actualization and other humanistic concepts, such as positive regard and self-worth, are difficult to demonstrate experimentally, critics argue that humanistic theories primarily describe how people behave rather than explain the causes of their behaviors. For these reasons, critics regard humanistic theories more as a wonderfully positive view of human nature or a very hopeful philosophy of life rather than as a scientific explanation of personality development (Burger, 2008). One major problem is that humanistic theories generally ignore research showing that 20% to 60% of the development of intellectual, emotional, social, and personality traits comes from genetic factors (Jang, 2005; McClearn et al., 1997; Parens et al., 2006). This means that genetic factors must be considered when discussing a person's true potential or a person's ability to achieve self-actualization.

Maslow hoped that humanistic theories would become a major force in psychology. Although the humanistic approach has not achieved Maslow's goal, humanism's ideas inspired the human potential movements in the 1960s–1970s and have been integrated into approaches for counseling, psychotherapy, and, as we learned with the Freedom Writers, education (Clay, 2002). Humanistic theories are becoming more widespread as ***positive psychology*** (p. 495), a relatively recent approach, is bringing humanistic ideas into the mainstream (Seligman & Csikszentmihalyi, 2000).

Concept Review

1. The combination of long-lasting and distinctive behaviors, thoughts, and emotions that are typical of how we react and adapt to other people and situations forms our ________________.

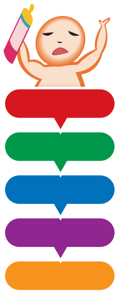
2. Freud's theory of personality, which emphasizes the importance of early childhood experiences and of conflicts between conscious thoughts and unconscious forces, is called a ________________ theory.

3. Freud developed three techniques for probing the unconscious. A technique that encourages clients to talk about any thoughts or images that enter their head is called (a) ________________. A technique to interpret the hidden meanings and symbols in dreams is called (b) ________________. With a third technique, the therapist analyzes the mistakes or (c) ________________ that the client makes in everyday speech.

4. Freud considered the mind to have three major divisions. The division that contains the biological drives and is the source of all psychic or mental energy is called the (a) ________________. This division operates according to the (b) ________________ principle, which demands immediate satisfaction. The division that develops from the id during infancy and whose goal is finding safe and socially acceptable ways of satisfying the id's desires is called the (c) ________________. This division operates according to the (d) ________________ principle, which involves satisfying a wish only if there is a socially acceptable outlet. The division that develops from the id during early childhood and whose goal is applying the moral values and standards of one's parents and society is called the (e) ________________.

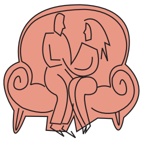
5. Conflicts between the id and the superego over satisfaction of desires may cause the ego to feel threatened. When threatened, the ego generates an unpleasant state that is associated with feelings of uneasiness, apprehension, and heightened physiological arousal; this unpleasant state is called (a) ________________. Freud suggested that the ego may reduce anxiety by using unconscious mechanisms that produce self-deception; these are called (b) ________________.

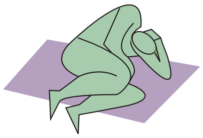
6. Freud proposed that the major influence on personality development occurs as we pass through five developmental periods that he called the (a) ________________ stages, each of which results in conflicts between the child's wishes and parents' restrictions. The result of a person's wishes being overgratified or undergratified at any one of the first three stages is called (b) ________________.



7. Personality theories that emphasize our capacity for personal growth, the development of our potential, and freedom to choose our destinies are referred to as ________________ theories.

8. Humanistic theories have three characteristics in common. They take the perspective that our perception of the world, whether or not it is accurate, becomes our reality; this is called the (a) ________________ perspective. Humanistic theories see personality as more than the sum of individual parts and consider personality as a unique and total entity that functions as a unit; this is the (b) ________________ view of personality. Humanistic theories point to an inherent tendency that each of us has to reach our true potential; this tendency is called (c) ________________.





9. The idea that our needs occur in ascending order, with biological needs at the bottom and social and personal needs toward the top, and that we must meet our lower-level needs before we can satisfy higher ones is called (a) ________________. Our physiological needs (food, sleep) and psychological needs (safety, belongingness, esteem) are called (b) ________________ needs because we try to fulfill them if they are not met. The highest need of self-actualization, which includes the desire for truth, goodness, beauty, and justice, is called a (c) ________________ need.

10. Carl Rogers's self theory of personality makes two basic assumptions. The first is that personality development is guided by an inborn tendency to develop our potential; this idea is called (a) ________________. The second assumption is that each of us has a personal need for acceptance and love, which Rogers called (b) ________________. According to Rogers, it is important that we receive love and acceptance despite the fact that we sometimes behave in ways that are different from what others think or value; this type of acceptance is called (c) ________________.

11. Rogers proposes that we have two kinds of selves: the self that is based on real-life experiences is called the (a) ________________ self; the self that is based on how we would like to see ourselves is called the (b) ________________ self.

Answers: *1. personality; 2. psychodynamic; 3. (a) free association, (b) dream interpretation, (c) Freudian slips or slips of the tongue; 4. (a) id, (b) pleasure, (c) ego, (d) reality, (e) superego; 5. (a) anxiety, (b) defense mechanisms; 6. (a) psychosexual, (b) fixation; 7. humanistic; 8. (a) phenomenological, (b) holistic, (c) self-actualization; 9. (a) Maslow's hierarchy of needs, (b) deficiency, (c) growth; 10. (a) self-actualization, (b) positive regard, (c) unconditional positive regard; 11. (a) real, (b) ideal*

F. Cultural Diversity: Unexpected High Achievement

Boat People: Remarkable Achievement

What was different about these children?

We have always been puzzled by why students with similar academic skills perform so differently: Some do well on our exams, while others do poorly. A humanist would look at the same differences and ask, "Why are some students developing their potential, while others are not?" One answer comes from studying thousands of Indo-Chinese refugees, known as the boat people, who were allowed to resettle in the United States in the 1970s and 1980s.

On their arrival in America, the boat people's only possessions were the clothes they wore. They knew virtually no English, had almost no knowledge of Western culture, and had no one to turn to for social or financial support. In spite of horrendous difficulties, refugee children achieved such remarkable academic success that American educators were scratching their heads and asking why.

© Jason Goltz

Refugee boat people's children, who first had to learn English, went on to achieve remarkable academic success.

Background. Researchers set out to discover why these refugee children had achieved astonishing scholastic success against overwhelming odds (N. Caplan et al., 1992). The researchers selected a random sample of 200 Indo-Chinese refugee families with a total of 536 school-age children. The children had been in the United States for an average of 3½ years. They had generally lived in low-income metropolitan areas with troublesome neighborhoods and rundown schools that were plagued with problems and not known for their high academic standards. Despite all these problems, the children of the boat people performed remarkably well in school. Here's what researchers found.

Amazing success. The researchers computed the mean grade point average for the 536 children, who were fairly evenly distributed among grades 1 to 12. They found that 27% of the children had a grade point average (GPA) in the A range, 52% had a GPA in the B range, 17% in the C range, and only 4% had a GPA below C. Equally noteworthy was the children's overall performance in math: Almost 50% of the children earned A's, while another 33% earned B's. On national math tests, the Indo-Chinese children's average scores were almost three times higher than the national norm.

After analyzing all these data, researchers were able to identify several reasons immigrant Indo-Chinese students achieved such high grades.

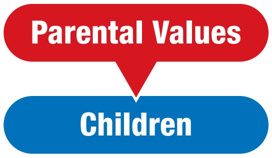
Values and Motivation

What were their values?

Although Indo-Chinese refugee children had been in the United States for an average of only 3½ years, they were doing better in math than 90% of their peers. It could not be the quality of their schools, which were average, undistinguished low-income schools in metropolitan areas. But clearly there were powerful factors helping these children overcome the problems of learning a second language and adapting to a new culture. Researchers located these powerful factors in the values of the Asian family.

The ***primary values*** held by the Indo-Chinese families were that parents and children have mutual respect, cooperate freely, and are committed to accomplishment and achievement. A clear example of commitment to accomplishment was the amount of time Indo-Chinese children spent doing homework: They averaged about 3 hours a day, while American students averaged about 1½ hours. Thus, among refugee families, doing homework, not watching television, was the main activity; the older children helped the younger children.

Another primary value is that parents were very involved in their children's education: Over 50% of parents read aloud and helped with homework. When children were asked, "What accounts for your academic success?" the children most often checked the category "having a love of learning." Love of learning was one of the values nourished and passed on from parent to child. When children were asked, "How much do you choose your own destiny?" the children answered that they did not trust luck or fate but were the masters of their own destinies.



Parental values on the importance of education motivated the children.

Parental Attitudes

How did parents help?

One reason Indo-Chinese children earned great academic success was the personal and cultural values transmitted by their parents, who were committed to help their children succeed through educational performance. After studying the immigrant parents' values and how they instilled these values in their children, researchers concluded that for American schools to succeed, parents must become more committed to the education of their children. In this case, Americans can truly learn from the values of these refugees.

In explaining the immigrant children's wonderful academic achievement, humanists would emphasize how parental values served to remove mental roadblocks that otherwise might have hindered their children from developing their true potentials and reaching self-fulfillment.

Next, we turn to a relatively common personality problem, shyness, and discuss how different theories of personality explain its causes.

Photo Credit: © Jason Goltz

G. Research Focus: Shyness

What Is Shyness and What Causes It?

What's it like to be shy?

It's one thing to discuss Freud's psychodynamic theory of personality, but it's another to see it in action—in this case, to treat shyness.

At some time and in some situations, we have all felt a little shy. However, there are degrees of shyness, and a high degree of shyness can interfere with enjoying personal and social interactions. For example, when Alan was a child, he would walk home from school through alleys to avoid meeting any of his classmates. Although he received a perfect math score on his SAT, he dropped out of the University of Texas because he always felt like a stranger and was continually frustrated by not being able to reach out and make contact with people. He was so shy that he could not even use the Internet. Finally, feeling so lonely, Alan sought help at the Shyness Clinic, which was founded in the 1970s by well-known shyness researcher, Philip Zimbardo of Stanford University (Noriyuki, 1996).

Shyness **is a feeling of distress that comes from being tense, stressed, or awkward in social situations and from worrying about and fearing rejection.**

Surveys indicate that about 40% of adults report mild but chronic shyness and, although they are good at hiding their shyness, internally they feel distress. About 20% report more severe shyness and are unable to hide their pain and distress (Chavira et al., 2002). The cause and treatment for shyness depend partly on which theory of personality guides our thinking. We'll contrast answers from two different theories: Freud's psychodynamic theory and social cognitive theory.

20–60% are shy.

Psychodynamic Approach

Is shyness due to unresolved conflicts?

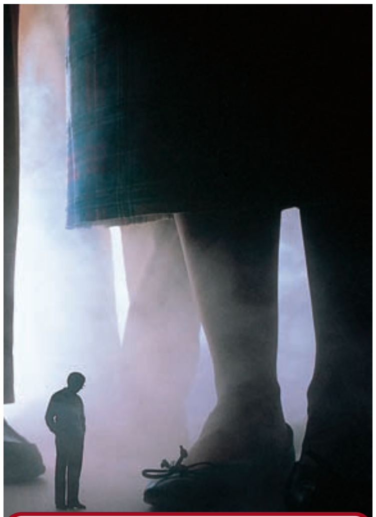
As a practicing psychoanalyst, Donald Kaplan (1972) uses his clinical experience and psychodynamic concepts to answer the question, What causes shyness? Kaplan traces the causes of shyness back to ***unresolved conflicts*** at one or more of Freud's psychosexual stages. For example, one very shy client reported that his mother constantly fed him so that he would never cry or whimper. As a result, Kaplan suggests that this client's unresolved conflict during the oral stage resulted in his feelings of inadequacy and shyness in later social interactions.

According to Kaplan, the symptoms of shyness include both conscious fears, such as having nothing to say, and unconscious fears of being rejected. Shy people may deal with these anxieties by using ***defense mechanisms;*** for example, one client reduced his anxiety through displacement, by changing his fears of being rejected into opposite feelings of self-righteousness and contempt.

One ***advantage*** of the psychodynamic approach is that it suggests that a number of causes, such as conscious and unconscious fears as well as unresolved psychosexual conflicts, are involved in shyness.

One ***disadvantage*** of the psychodynamic approach is that Freudian concepts (unconscious fears, unresolved psychosexual stages) are difficult to verify by experimental methods (E. F. Torrey, 2005). For example, saying that being fixated at the oral stage may result in a person becoming a shy adult is mostly a descriptive guess rather than a testable hypothesis.

A very different account of what causes shyness comes from the social cognitive theory of personality.



The cause and treatment for shyness depend partly on which theory of personality the therapist follows.

Social Cognitive Theory

What are the three factors?

Unlike the Freudian approach, which relies primarily on therapists' personal observations, social cognitive theory uses primarily experimental studies to answer questions about personality. Social cognitive theory breaks shyness down into three measurable or observable components—cognitive, behavioral, and environmental—which can be studied using the experimental method described in Module 2 (Chavira et al., 2002). For example, in a series of longitudinal studies, researchers found that about 10–15% of the population have a shy personality that, to a large extent, comes from ***genetic factors***—for example, inheriting a nervous system that is easily aroused by novel stimuli (Battaglia, 2005; Kagan, 2003a). By observing the social interactions (the behavioral component) of shy people, researchers found that shy people have too few social and communication skills and, as a consequence, they are continually punished during social interactions (Gabrieli, 2005; Putnam, 2005). By giving personality tests (the cognitive component), researchers found that shy people are overly self-conscious, which leads to worrisome thoughts and irrational beliefs that interfere with social functioning (Romney & Bynner, 1997). Therapies based on social cognitive theory (Module 20) have proved successful in helping shy individuals decrease their anxiety in social situations, develop better social skills, and decrease levels of shyness (Greco & Morris, 2001; Kluger, 2005).

One ***advantage*** of social cognitive theory is that it breaks shyness down into three measurable or observable components, which can be experimentally studied and appropriate treatments developed.

One ***disadvantage*** of this approach is that researchers may overlook certain influences that we are neither conscious nor aware of, such as how our brain processes emotions or experiences conditioned emotional responses, both of which can trigger shy behaviors (Theall-Honey & Schmidt, 2006; Westen, 1998).

Our discussion of shyness raises the interesting question of how psychologists measure or assess personality traits, such as shyness.

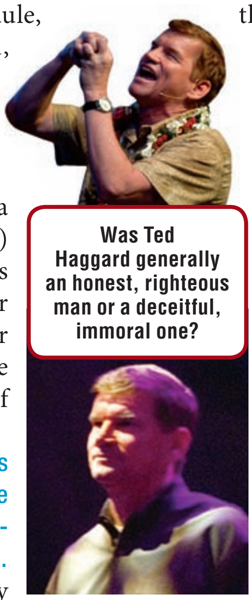
H. Application: Assessment—Projective Tests

Definition of Projective Tests

How did friends describe Ted's personality?

At the beginning of this module, we discussed Ted Haggard, the 50-year-old pastor, who at the height of his career confessed to committing infidelity with a male prostitute. When a close friend described Haggard's personality, he said that Ted was a family man who followed God's word (top photo) (Goodstein & Banerjee, 2006). Before the accusations against Ted were made, none of his family, friends, or colleagues described him as a deceitful, dishonest, or immoral individual (bottom photo). When friends were describing Ted's personality, they were making a kind of psychological assessment.



Was Ted Haggard generally an honest, righteous man or a deceitful, immoral one?

Psychological assessment refers to the use of various tools, such as psychological tests or interviews, to measure various characteristics, traits, or abilities in order to understand behaviors and predict future performances or behaviors.

Psychological tests are usually divided into ability tests and personality tests, which differ considerably. For example, when people enter a psychological or drug treatment program, they are most likely given personality tests to identify their personal problems.

Personality tests are used to measure observable or overt traits and behaviors as well as unobservable or covert characteristics. Personality tests are used to identify personality problems and psychological disorders as well as to predict how a person might behave in the future.

Although you may not have taken a personality test, you certainly have taken many ability tests, such as exams.

Ability tests include achievement tests, which measure what we have learned; aptitude tests, which measure our potential for learning or acquiring a specific skill; and intelligence tests, which measure our general potential to solve problems, think abstractly, and profit from experience (R. M. Kaplan & Saccuzzo, 2009).

The primary tools of assessment are tests of ability and personality. There are two kinds of personality tests. We'll now focus on one kind, projective personality tests, and later (p. 474) discuss objective personality tests. Personality assessment is a $400-million-a-year industry (Gladwell, 2004).

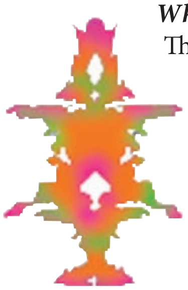
Examples of Projective Tests

In describing Haggard's personality, we can identify observable behaviors, such as happy, family-oriented, and friendly, as well as unobservable behaviors, such as anxious, guilt-ridden, and deceitful. In Freud's psychodynamic theory, observable behaviors reflect conscious wishes, desires, and thoughts, while unobservable behaviors may reflect unconscious forces. Freud developed three techniques for revealing unconscious forces—free association, dream interpretation, and interpretation of slips of the tongue. We now add a fourth technique to reveal hidden or unconscious forces: projective tests.

Projective tests require individuals to look at some meaningless object or ambiguous photo and describe what they see. In describing or making up a story about the ambiguous object, individuals are assumed to project both their conscious and unconscious feelings, needs, and motives.

Although Freud didn't develop projective tests, they are assumed to reveal unconscious thoughts (Butcher, 2009b; Groth-Marnat, 2009). We'll examine two widely used projective tests—Rorschach *(ROAR-shock)* inkblot test and Thematic Apperception Test (TAT).

Rorschach Inkblot Test



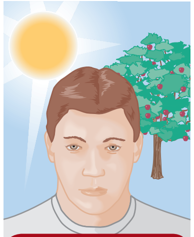
What might this be?

What do you see in this inkblot? The Rorschach inkblot test, which was published in the early 1920s by a Swiss psychiatrist, Hermann Rorschach (1921/1942), contains five inkblots printed in black and white and five that have color (the inkblot shown on the left is similar to but is not an actual Rorschach inkblot).

The ***Rorschach inkblot test*** is used to assess personality by showing a person a series of ten inkblots and then asking the person to describe what he or she thinks each image is.

This test is used primarily in the therapeutic setting to assess personality traits and identify potential problems of clients (I. B. Weiner & Meyer, 2009).

Thematic Apperception Test (TAT)



What's happening in this picture?

What's happening in this picture? A person would be shown a picture like the one on the right and asked to make up a plot or story about what the young man is thinking, feeling, or doing. This is an example of, but not a real, TAT card.

The ***Thematic Apperception Test,*** or ***TAT,*** involves showing a person a series of 20 pictures of people in ambiguous situations and asking the person to make up a story about what the people are doing or thinking in each situation.

The TAT, which was developed by Henry Murray (1943), is used to assess the motivation and personality characteristics of normal individuals as well as clients with personality problems (Butcher, 2009a; R. M. Kaplan & Saccuzzo, 2009).

Before we discuss how well the Rorschach inkblot test and the TAT assess personality traits and identify potential problems, we'll look at another personality test that you have probably heard of: handwriting analysis. How much can someone learn from just your handwriting?

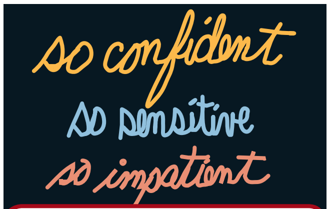
Two Characteristics

What does handwriting show?

Handwriting analysts (graphologists) charge about $75 an hour to do personality assessments that they claim reveal a person's strengths and weaknesses, which are important in selecting job applicants and identifying people who may not be trusted (M. C. Healy, 2005; Scanlon & Mauro, 1992).

However, researchers report that handwriting analysis is no better than chance at assessing personality characteristics, rating the success of job applicants, or identifying one's profession (M. C. Healy, 2005; Tripician, 2000). In order for handwriting analysis or any personality assessment test to be an effective personality assessment tool, it must have two characteristics: validity and reliability. Handwriting analysis is no better than chance in assessing personality because it lacks validity.



Which handwriting reveals an honest and sincere person?

Validity

Handwriting analysis is fun but no better than chance as a personality test because it lacks validity.

Validity **means that the test measures what it says it measures or what it is supposed to measure.**

For example, for a personality test to be valid, it must measure personality traits specific to the person rather than general traits that apply to almost everyone. Handwriting analysis does not measure, identify, or predict traits specific to an individual, so it has no validity as a personality test (M. C. Healy, 2005; Tripician, 2000).

In addition to validity, a good personality test must have a second characteristic, reliability.

Reliability

In judging the usefulness of any personality test, the major question is always the same: How good are the test's validity and reliability?

Reliability **refers to having a consistent score at different times. A person who takes a test at one point in time should receive the same score on a similar test taken at a later time.**

For example, handwriting analysis may have good reliability provided your handwriting remains about the same across time. But, even if handwriting analysis has good reliability, it is still no better than chance at assessing or predicting an individual's personality traits because graphology lacks the important characteristic of validity.

This means that the usefulness of projective personality tests, such as the Rorschach test and TAT, depends on their validity and reliability.

Usefulness of Projective Tests

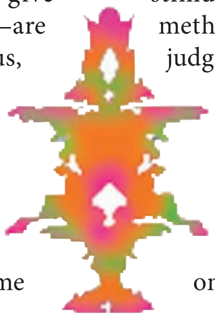
Are they valid and reliable?

Projective tests, such as the Rorschach inkblot test, have been used for over 80 years. However, there is still a debate between therapists, who report that projective tests are useful in assessing personality traits and problems, and researchers, who continue to disagree about the reliability and validity of projective tests (Mestel, 2003b; Society for Personality Assessment, 2005). This debate involves the advantages and disadvantages of projective tests.

Advantages

Individuals who take projective tests do not know which are the best, correct, or socially desirable answers to give because the stimuli—the inkblot or the TAT picture—are ambiguous and have no right or wrong answers. Thus, one advantage of projective tests such as the Rorschach and the TAT is that they are difficult to fake or bias, since there are no correct or socially desirable answers.

When clients respond to Rorschach's meaningless inkblots or make up stories about what is happening in TAT's ambiguous pictures, clinicians assume that clients project their hidden feelings, thoughts, or emotions onto these ambiguous stimuli. Based on this assumption, some clinicians believe that a second advantage of projective tests is that they are another method for assessing a client's hidden and unconscious thoughts and desires of which he or she is normally unaware (Groth-Marnat, 2009). Other researchers suggest that the Rorschach test is useful as an interview technique in eliciting unique information about the person (Aronow et al., 1995). Thus, the Rorschach test's advantage is obtaining information about the person in a setting where there are no right or wrong answers.



Clinicians' experience affects reliability and validity of projective tests.

Disadvantages

One disadvantage of projective tests comes from their use of ambiguous stimuli to which there are no right or wrong answers. The current method of scoring the Rorschach is based on analyzing and making judgments about so many different variables (such as content, theme, color, and detail of the cards) that disagreements often arise over interpretations and classifications (Mestel, 2003b). For example, there are several studies using the Rorschach in which clinicians scored and interpreted the results as indicating that perfectly normal individuals were classified as psychologically disordered (J. M. Wood et al., 2003). Although the Rorschach is one of the more popular personality assessment tests and some studies show it has high reliability and validity, there are other studies that point to serious problems in scoring and interpreting responses and making assessments based on the Rorschach test (Society for Personality Assessment, 2005; J. M. Wood et al., 2003, 2006).

In spite of criticisms, some experienced clinicians report that projective tests can provide reliable and valid information about a client's personality and problems, especially when combined with other assessment techniques (Exner & Erdberg, 2005). Thus, a clinician's training and experience play a major role in the accuracy of assessing a client's personality and problems using projective tests (R. M. Kaplan & Saccuzzo, 2009).

Summary Test

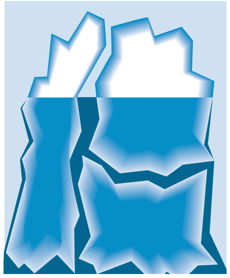
A. Freud's Psychodynamic Theory

1. The lasting behaviors, thoughts, and emotions that typify how we react and adapt to other people and situations make up our (a) ________________. An organized attempt to explain how personalities develop and why they differ is called a (b) ________________ of personality.

2. Freud's approach, which emphasizes the importance of early childhood experiences and conflicts between conscious and unconscious forces, is called a (a) ________________ theory of personality. According to Freud, those wishes, desires, or thoughts of which we are aware or that we can readily recall are (b) ________________; those that we automatically repress because of their disturbing or threatening content are (c) ________________.

3. Freud's technique of encouraging clients to talk about any thoughts or images that enter their heads is called (a) ________________. His assumption that dreams provide clues to unconscious thoughts and desires gave rise to his technique of (b) ________________. Mistakes that we make in everyday speech that are thought to reflect unconscious thoughts or wishes are called (c) ________________.

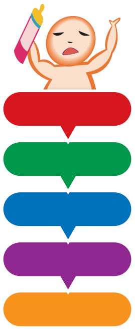
B. Divisions of the Mind



4. According to Freud, the biological drives of sex and aggression are the source of all psychic or mental energy and give rise to the development of the (a) ________________. Because this division of the mind strives to satisfy drives and avoid pain without concern for moral or social restrictions, it is said to be operating according to the (b) ________________. During infancy, the second division of the mind develops from the id; it is called the (c) ________________. The goal of this second division is to find safe and socially acceptable ways of satisfying the id's desires. The ego follows a policy of satisfying a wish or desire only if a socially acceptable outlet is available; thus it is said to operate according to the (d) ________________. During early childhood, the third division of the mind develops from the id; it is called the (e) ________________. The goal of this division is to apply the moral values and standards of one's parents and society in satisfying one's wishes.

5. When the id, ego, and superego are in conflict, an unpleasant state of uneasiness, apprehension, and heightened physiological arousal may occur; this is known as (a) ________________. The Freudian processes that operate at unconscious levels to help the ego reduce anxiety through self-deception are called (b) ________________; they can be helpful or harmful, depending on how much we rely on them.

C. Developmental Stages



6. The essence of Freud's theory of personality development is a series of five developmental stages, called (a) ________________, during which the individual seeks pleasure from different parts of the body. The stage that lasts for the first 18 months of life is called the (b) ________________ stage. It is followed by the (c) ________________ stage, which lasts until about the age of 3. The next stage, until about the age of 6, is called the (d) ________________ stage. The stage that lasts from about 6 to puberty is called the (e) ________________ stage; it is followed by the (f) ________________ stage, which lasts through adulthood.

7. The resolution of the potential conflict at each stage has important implications for personality. A Freudian process through which individuals may be locked into earlier psychosexual stages because their wishes were overgratified or undergratified is called ________________; it can occur at any of the first three stages.

D. Freud's Followers & Critics

ego
superego
id
psychosexual
fixation

8. Jung believed that the basic force is not the sex drive, as Freud believed, but ancient memory traces and symbols shared by all peoples in all cultures, called the (a) ________________. According to Adler's philosophy, each person is a social being with a unique personality and is motivated by (b) ________________. Karen Horney disagreed with Freud's emphasis on biological urges and insisted that the major influence on personality development was (c) ________________ between parents and child.

9. Those who generally agreed with Freud's basic ideas but disagreed with his emphasis on biological forces, sexual drives, and psychosexual stages are referred to as ________________. They turned the emphasis of psychodynamic theory to psychosocial and cultural influences.

10. Criticisms of Freud's psychodynamic theory include that it is so comprehensive that it is not very useful for explaining or predicting behaviors of a specific (a) ________________; that some Freudian ideas (Oedipal complex) are out of date because they cannot be (b) ________________; and that psychodynamic theory must be updated with findings about (c) ________________ factors and the association between (d) ________________ development and related behaviors.

E. Humanistic Theories

11. Humanistic theories emphasize our capacity for personal growth, development of our potential, and freedom to choose our (a) ____________. They stress that our perception of the world becomes our reality; this is called the (b) ____________ perspective. These theories emphasize that one's personality is unique, functions as a unit, and is more than the sum of individual parts; together these ideas make up the (c) ____________ view. These theories also highlight the idea of an inherent tendency to reach our true potentials, which is called (d) ____________.

12. According to Maslow, our needs are arranged in a hierarchy with (a) ____________ at the bottom and (b) ____________ toward the top.

13. How we see or describe ourselves, including how we perceive our abilities, personality characteristics, and behaviors, is referred to as our (a) ____________. According to Carl Rogers, the development of self-concept depends on our interactions with others. If we receive (b) ____________ positive regard even when our behavior is disappointing, we will develop a positive self-concept and tend to act, feel, and think optimistically and constructively.

F. Cultural Diversity: Unexpected High Achievement

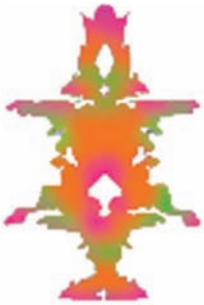
© Jason Goltz

14. Indo-Chinese children overcame problems of language and culture and excelled in American schools in part because of the ____________ held by their families, including mutual respect, cooperation, parental involvement, and the belief that they, not fate, controlled their destinies.

G. Research Focus: Shyness

15. As a practicing psychoanalyst, Donald Kaplan traces the causes of shyness back to unresolved conflicts at one or more of Freud's (a) ____________. The Freudian approach primarily uses therapists' (b) ____________ to answer questions about personality. In comparison, social cognitive theory breaks shyness down into three measurable or observable components that can be investigated using (c) ____________.

H. Application: Assessment—Projective Tests



16. Tests that are used to measure observable traits and behaviors as well as unobservable characteristics of a person and to identify personality problems and psychological disorders are called ____________ tests.

17. Achievement tests measure what we have learned; aptitude tests measure our potential for learning or acquiring a specific skill; and intelligence tests measure our general potential to solve problems, think abstractly, and profit from experience. Collectively, these are called ____________ tests.

18. For a test to be useful, it must have two characteristics. First, a test must measure what it is supposed to measure; this is called (a) ____________. Second, a person's score on a test at one point in time should be similar to the score obtained by the same person on a similar test at a later point in time; this is called (b) ____________.

19. Typically, a combination of tests is used to assess personality. Tests that involve presenting an ambiguous stimulus and asking the person to describe it are called (a) ____________ tests. A test used to assess personality in terms of how the subject interprets a series of inkblots is called the (b) ____________ test. A test in which the subject is to make up a story about people shown in ambiguous situations is called the (c) ____________.

***Answers:** 1. (a) personalities, (b) theory; 2. (a) psychodynamic, (b) conscious thoughts, (c) unconscious forces or thoughts; 3. (a) free association, (b) dream interpretation, (c) slips of the tongue or Freudian slips; 4. (a) id, (b) pleasure principle, (c) ego, (d) reality principle, (e) superego; 5. (a) anxiety, (b) defense mechanisms; 6. (a) psychosexual stages, (b) oral, (c) anal, (d) phallic, (e) latency, (f) genital; 7. fixation; 8. (a) collective unconscious, (b) social urges, (c) social interactions; 9. neo-Freudians; 10. (a) individual or person, (b) tested or verified, (c) genetic, (d) brain; 11. (a) destinies, (b) phenomenological, (c) holistic, (d) self-actualization; 12. (a) biological needs, (b) social and personal needs; 13. (a) self or self-concept, (b) unconditional; 14. primary values; 15. (a) psychosexual stages, (b) personal observations, (c) experimental studies; 16. personality; 17. ability; 18. (a) validity, (b) reliability; 19. (a) projective, (b) Rorschach inkblot, (c) Thematic Apperception Test (TAT)*

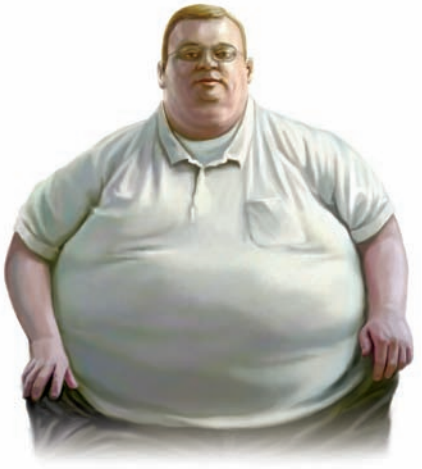
Critical Thinking

Can Personality Explain Obesity?

About two of every three American adults are overweight or obese. Peter Herida is one of the very few who is medically defined as "super massive morbid obese." As a 10–12-year-old child, Peter already weighed 179 pounds. At age 46, his weight reached an astonishing 863 pounds (pictured at right). His grocery bill was nearly $400 a week, and he ate over 3,000 calories at each meal. Peter took 14 different medications four times a day because of the life-threatening health damage caused by his extreme morbid obesity. Some of Peter's medical problems included heart failure, diabetes, and difficulty breathing during sleep. He became so heavy he could not walk, which resulted in him being housebound for 20 years. His mobility became so limited that a trip to the doctor's office required a wheelchair van, two fire truck crews, and one ambulance crew to transport him.



During one doctor's visit, Peter was told that unless he took radical measures to lose weight quickly, he would die soon. Peter chose to undergo gastric bypass surgery, a risky procedure that promised to make his stomach smaller so he would feel full after eating much less food. His doctor warned him that because of his weight and health problems, the operation carried a 60% chance of death. So, when Peter woke up after surgery, he promised himself, "I'm going to try and make this thing work, as I now was given a second chance at life!" (Herida, 2003).

Peter knew the operation was the easy part and the challenging part would be to make long-term lifestyle changes. After not having moved his body for 20 years, Peter spent his first 3 months learning how to walk again. He exercised and dieted for years afterward. At age 49, he swims a mile a day and works out daily. His health improved so much he takes only two medications a day compared to the 14 he took before. He is no longer a diabetic, he sleeps without difficulty breathing, and his heart is functioning better.

Peter's efforts helped him to lose a whopping 560 pounds during the first 10 months after surgery. His self-esteem skyrocketed and he rewarded himself by purchasing his dream car, a mint-condition 1982 Mercedes sedan, which he says "beats the heck out of a wheelchair van and emergency vehicle motorcade" (Herida, 2005). Peter became a motivational speaker to encourage others to strive to reach their potential just as he did. (Adapted from Herida, 2003, 2005; Incredible weight loss stories, 2007; Taneeru, 2006)

QUESTIONS

1 Which part of Freud's psychodynamic theory might explain why Peter could not control his eating?

2 Does Peter have a food addiction?

3 What roles might the Freudian concepts of the id, ego, and superego have had in Peter becoming so obese that he could not walk?

4 Following Freud's psychodynamic theory, what kinds of questions might you ask or what techniques might you use to understand Peter's overeating behavior?

5 What psychological impulses or conflicts may have made losing weight difficult for Peter?

6 How might humanistic theories explain Peter's obesity and then the dramatic changes he made in his life?

Suggested Answers to Critical Thinking

1. The part of Freud's psychodynamic theory that focuses on the development of personality involves how a person goes through the five psychosexual stages and whether fixation occurs. For example, Peter may have become fixated at the oral stage, resulting in the inability to control his eating.
2. We can't be sure Peter has a food addiction because obesity is only suspected to result from an addiction to food. Preliminary research suggests obese people may be compulsively driven to eat food just as drug addicts are driven to use drugs. More research on the neurological connections between overeating and addiction is necessary.
3. Peter's id, which follows the pleasure principle, wanted to eat all the time. Peter's superego, which contains moral standards, would argue against overeating because it jeopardizes health and well-being. Peter's ego, which follows the reality principle, would try to find a socially acceptable outlet for the id's desires. In Peter's case, the id's desires apparently won out.
4. Since Freud believed that most personality development and seeds of problems occurred during the first five years, you would ask questions about his early childhood, especially his relationship with his parents. To reveal Peter's unconscious forces, you might use free association and dream interpretation.
5. Psychological impulses or conflicts that may have led to Peter's overeating and may make losing weight challenging include anxiety, tension, worry, and insecurity. Also, overeating was likely a means of achieving pleasure, gratification, and excitement.
6. Humanistic theories describe positive human growth. However, a humanist might say that because Peter had not received enough unconditional positive regard, he developed a negative self-concept, which interfered with his self-actualization and led him to overeat. A humanist would also say we all have the capacity for self-actualization and reaching our own potential, which for Peter was achieving a healthy weight and lifestyle.

Power of Beliefs

Why did she get threatened, clubbed, and jailed?

She chose to be tortured and jailed rather than change her major beliefs.

Wangari Maathai *(wan-GAH-ree mah-DHEYE)* was born in Kenya into a family of peasant farmers. She grew up in a beautiful countryside filled with many varieties of shrubs and trees. Water cascaded down to streams where she drank to quench her thirst. According to Kenyan tradition, as the oldest daughter, Maathai spent most of her days side by side with her mother, helping her and learning from her. She later made a bold decision to break with cultural expectations and study in the United States, where she earned both bachelor's and master's degrees. Upon returning home, Maathai yet again challenged cultural expectations by becoming the first woman in Kenya to earn a Ph.D. and later the first female professor at the University of Nairobi.

When Maathai returned to Kenya, she realized there were fewer and fewer of the magnificent trees that once filled the region. One day she went to her yard and planted a tree, and it was then that she founded the Green Belt Movement, an organization that helps conserve the environment, educates people about environmental issues, and trains women to have jobs as nursery managers and forest rangers. Maathai empowered women by letting them plant their own trees and make profits from the products (nuts, fruits) to support their children's education and household needs.

As Maathai began her efforts to restore nature, she quickly realized that the government in Kenya was corrupt and was largely responsible for the deforestation by illegally selling land and trees to make room for buildings. The Green Belt Movement challenged the government's abuse of power, corruption, and destruction of the environment. Maathai initiated sit-ins and a hunger strike but was attacked with tear gas and viciously clubbed by police. On one occasion she was beaten unconscious. She received many death threats, was arrested more than a dozen times, and once even went into hiding.

Despite the brutality she experienced time and time again, Maathai persisted in her struggle for human rights and environmental conservation. Today, the Green Belt Movement has planted 30 million trees in Kenya and provided work for tens of thousands of women. Her unwavering dedication, absolute selflessness, and inspiring courage led her to receive many honors. In 2004, Maathai became the first African woman to win the Nobel Peace Prize (adapted from Maathai, 2004, 2005, 2006; Mjøs, 2004).

What were the forces that shaped Maathai's personality and gave her the strength and motivation to persist in the face of overwhelming adversity? In this module, we'll discuss some forces that shape and mold our personalities.

In a different nation, an ocean away, Kiran Bedi waged her own personal struggle against forces that said no Indian woman should be doing what she wanted to do.

Determination

What's unusual about this woman?

At just 5 feet 3 inches, Kiran Bedi wouldn't normally attract much attention. Yet, with her petite stature and only a wooden baton, she once turned back a 3,000-member, sword-wielding group of rioters by herself. Her male colleagues felt overwhelmed and ran away.

In 1972, Kiran Bedi became India's first female police officer. Sure, she faced criticism from her male counterparts who believed she didn't have the physical strength or mental toughness the job required. But, she never let their negative comments hold her back.

Bedi began her service in the traffic division and made headlines when she towed the illegally parked cars of government officials. She later worked as a narcotics officer and antiterrorist specialist. She even reformed the largest prison in Asia, and her work there has led to prison reform all over the world. From the beginning of her career, she believed the duty of police officers was not to simply catch the bad guys but to show people the way to a better life.

Kiran Bedi fought against stereotypes to fulfill her dream.

In India, a country where women struggle to achieve gender equality, Bedi's unyielding determination didn't go unnoticed. She has received many prestigious awards for her achievements, including the Asian version of the Nobel Prize. She has become a hero and role model for Indian women, as well as all women living in countries where the struggle for gender equality continues. Bedi has taught women that with determination they can overcome criticisms and stereotypes to realize their dreams (Bedi, 2006; Turnbull, 2008).

Kiran Bedi, like the many thousands of female officers around the world, has shown that women make good cops, partly because of their particular personality traits: Women are less authoritarian, more open, better listeners, and less likely to trigger showdowns than are their male counterparts (Lonsway et al., 2003; Munoz, 2003). Apparently, what women may lack in sheer muscle power, they make up for in a winning combination of personality traits.

In this module, we'll discuss personality traits, which are powerful motivating forces that we all have, cannot live without, like to talk about, and are often asked to change but find it difficult to do so.

What's Coming

We'll discuss two theories of personality, each with a different emphasis. The first is social cognitive theory (previously called social learning theory), which stresses the influences of cognitive, learning, and social processes on personality development. The second is trait theory, which focuses on measuring traits and describing how traits make up our different personalities and influence our behaviors.

We'll begin with three social cognitive forces that helped shape Wangari Maathai's personality.

A. Social Cognitive Theory

Review and Definition

What shaped her personality?

How many of us would still have fought to protect the environment after being beaten repeatedly, having our life threatened, and being imprisoned more than a dozen times, as Maathai did? What forces shaped Maathai's personality and gave her such courage, self-confidence, and perseverance? In Module 19, we discussed two approaches to this question: Freud's psychodynamic theory and humanistic theories.

Freud's psychodynamic theory said that our personality is shaped primarily by our inborn biological urges, especially sex and aggression, and by how we resolve conflicts during the psychosexual stages, especially during the first five years.

Humanistic theories, such as those of Abraham Maslow and Carl Rogers, assume that we are basically good and that our personality is shaped primarily by our inborn tendency for self-actualization or self-fulfillment, which includes both biological and psychological factors.

Maathai won honors because of her unwavering courage.

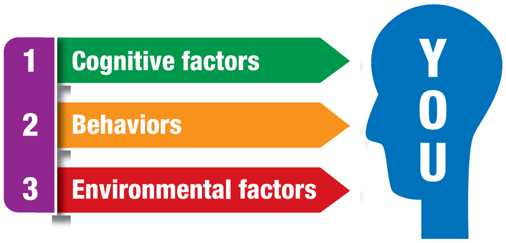
Now we discuss two more answers: first, social cognitive theory and, later, trait theory.

Social cognitive theory says that personality development is shaped primarily by three forces: environmental conditions (learning), cognitive-personal factors, and behavior, which all interact to influence how we evaluate, interpret, organize, and apply information.

Social cognitive theory grew out of the research of a number of psychologists, especially Albert Bandura (1986, 2001a). According to social cognitive theory, we are neither good nor bad but are shaped primarily by three influential factors.

Interaction of Three Factors

For about 30 years, Wangari Maathai has been fighting for human rights and environment conservation. During this time, she has suffered tremendous personal hardships, including being beaten and imprisoned. You can't help wondering what shaped her personality and gave her the strength, determination, and character to sacrifice so much to reach her goals of preserving the environment and empowering women. According to social cognitive theory, Maathai's personality was influenced and shaped by the interactions among three significant forces—namely, cognitive-personal, behavioral, and environmental factors.



Cognitive-Personal Factors

Maathai was born to a family of peasant farmers and grew up during a time when Kenya had an abundance of greenery. Her childhood experiences taught her the beauty of nature's wonders. Her family encouraged her to be self-confident, ambitious, and determined to achieve her dreams. Being born into a farming family and being taught to value nature are examples of cognitive-personal factors that helped shape Maathai's personality.

Cognitive factors include our beliefs, expectations, values, intentions, and social roles. ***Personal factors*** include our emotional makeup and our biological and genetic influences.

Cognitive factors guide personality development by influencing the way we view and interpret information. For example, Maathai views the world from the standpoint of someone whose livelihood depended on nature. These kinds of beliefs (cognitions) give Maathai the strength and determination to fight to plant more trees. Thus, cognitive-personal factors influence our personalities by affecting what we think, believe, and feel, which in turn affect how we act and behave.

Maathai plants trees because of cognitive-personal factors.

Behaviors

For the past 30 years, Maathai has spoken forcefully against deforestation, founded the Green Belt Movement, and empowered women by involving them in restoring the environment. These are examples of the kinds of behaviors that also shaped her personality.

Behaviors include a variety of personal actions, such as the things we do and say.

In Maathai's case, the political and social behaviors that she engaged in to help preserve the environment in turn strengthened her belief that the government's actions to replace greenery with buildings was morally and politically wrong.

Just as behavior influences our beliefs, so too does our environment influence both.

Environmental Factors

Maathai lived in Kenya at a time of political oppression, which resulted in harsh beatings, imprisonment, and sometimes death when speaking out against the government's corrupt actions. These environmental factors certainly affected Maathai's personality development.

Environmental factors include our social, political, and cultural influences, as well as our particular learning experiences.

Just as our cognitive factors influence how we perceive and interpret our environment, our environment in turn affects our beliefs, values, and social roles.

We can assume that living in such an oppressive environment strengthened Maathai's determination to get a Ph.D. and to devote her life to restoring trees and empowering women.

According to Bandura (2001a), personality development is influenced by the interactions among these three factors. He especially focused on cognitive-personal factors.

Bandura's Social Cognitive Theory

Why are beliefs important?

Albert Bandura (1986, 2001a) originally called his theory of personality development the social learning theory. However, to emphasize the importance of cognitive factors in personality development, he has changed the name to the social cognitive theory.

Bandura's social cognitive theory assumes that personality development, growth, and change are influenced by four distinctively human cognitive processes: highly developed language ability, observational learning, purposeful behavior, and self-analysis.

Bandura believes that these four cognitive processes reach their highest level of functioning in humans and that much of human personality and behavior is shaped by our own thoughts and beliefs.

Cognitive factors—beliefs, values, and goals—influence their personalities.

For example, the people in the photo on the left are members of Wangari Maathai's international Green Belt Movement. Maathai founded this organization over 30 years ago to help restore the environment all over the world while helping to empower women by getting them actively involved in the organization. According to Bandura's social cognitive theory, the personalities of these members will, to a large extent, be molded by cognitive factors such as the beliefs, values, and goals of the Green Belt Movement. We'll briefly explain each of Bandura's cognitive factors.

Four Cognitive Factors

At the heart of Bandura's social cognitive theory is the idea that much of personality development is shaped and molded by cognitive processes that influence how we view and interpret the world. And, in turn, how we view and interpret the world influences how we behave. Here's how Bandura's cognitive processes apply to Green Belt Movement members.

1 **Language ability.** This is a powerful tool for processing and understanding information that influences personality development. We turn this information into ideas, beliefs, values, and goals, which shape, guide, and motivate our behaviors. For example, the Green Belt Movement teaches and values restoring the environment and empowering women, which helps motivate members to be more nurturing, giving, and self-confident.

2 **Observational learning.** Almost all of us "people watch"; we observe parents, brothers, sisters, peers, friends, and teachers; by doing so, we learn a great deal. Observational learning involves watching, imitating, and modeling. Most of the time, the observer provides his or her own reward for developing some belief or performing some behavior. For example, observational learning allows the members of the Green Belt Movement to imitate and model the personality characteristics of Wangari Maathai.

3 **Purposeful behavior.** Our capacity to anticipate events, plan ahead, and set goals influences our personality development, growth, and change. For instance, in working to restore the environment, members of the Green Belt Movement organize and plan ways to plant more trees and speak firmly against deforestation, which encourages them to become responsible, confident, and passionate about their cause.

4 **Self-analysis.** This is an internal process that allows us to monitor our own thoughts and actions. By deciding to change our goals or values, we can affect our personality development. For instance, members of the Green Belt Movement may use self-analysis to check their personal progress and to reward themselves for meeting the organization's goals.

According to Bandura's social cognitive theory, these four cognitive processes influence our personality development, growth, and change.

To make the relationship between cognitive factors and personality more concrete, we'll focus on three specific beliefs: locus of control (this page), delay of gratification, and self-efficacy (next page).

Locus of Control

Can you control when you'll graduate?

This is the kind of question that intrigued Julian Rotter (1990), who was interested in how social cognitive theory applied to human behavior. Rotter developed a well-known scale to measure a person's expectancies about how much control he or she has over situations, which Rotter called the locus of control.

Locus of control refers to our beliefs about how much control we have over situations or rewards. We are said to have an *internal locus of control* if we believe that we have control over situations and rewards. We are said to have an *external locus of control* if we believe that we do not have control over situations and rewards and that events outside ourselves (fate) determine what happens. People fall on a continuum between internal and external locus of control.

Can you control when you will graduate?

For example, if you believe that when you graduate depends primarily on your motivation and determination, then you have more of an internal locus of control. If you believe that when you graduate depends mostly on chance or things outside your control, then you have more of an external locus of control. Having more of an internal locus of control is an advantage because hundreds of studies report a positive relationship between internal locus of control and psychological functioning. For example, people with an internal locus of control are generally higher achievers, cope better with chronic illness, and report less stress, anxiety, and depression than those with an external locus of control. Also, an internal locus of control during childhood seems to protect people against some health problems in adulthood (Burger, 2008; Gale et al., 2008; Livneh et al., 2004; Spector et al., 2001).

These findings indicate that a specific belief influences how you perceive your world, which, in turn, affects how you behave. Next, we'll examine two other beliefs that influence behavior.

A. Social Cognitive Theory

Delay of Gratification

Get it now or wait for better things?

Many young children have a difficult time not grabbing their favorite candy from the low-lying shelves at checkouts in spite of parents promising they'll get candy when they get home. Likewise, adults may see something they didn't intend to buy but do so on impulse, not always getting the best product or deal. These are common examples of the struggle with a cognitive concept or belief called delay of gratification.

Delay of gratification refers to not taking an immediate but less desirable reward and instead waiting and pursuing an object or completing a task that promises a better reward in the future.

Although related to the ideas of self-control, impulsiveness, and will power, delay of gratification is defined so that it can easily be studied in the laboratory (Mischel et al., 1989). One technique to measure delay of gratification was to show children two objects, one less preferred (a single marshmallow) and one more preferred (two marshmallows). The children were told that to obtain the more preferred reward they had to wait until the experimenter, who had to leave the room, returned after some delay (about 15 minutes). Children were free to end the waiting period by ringing a bell, but then they would get only the less preferred reward. Thus, the child had a real conflict: Accept immediate gratification and take the less preferred reward, or delay gratification and obtain the more preferred reward. How long children could wait depended upon what they attended to. If they pictured the marshmallows in their minds, they could wait about 15 minutes, but if the marshmallows were right in front of them, they waited only 6 minutes (Mischel et al., 1989).

Should I take one marshmallow now or wait and get two later?

Important to delay gratification? Researchers found that the ability to delay gratification influenced many behaviors. For example, 4-year-old children good at delaying gratification tended to be more intelligent, to have greater social responsibility, and to strive for higher achievement. When these very same 4-year-old children were later retested at age 14, they were rated by parents as more competent, more intelligent, and better able to concentrate than those children who were not good at delaying gratification. NOT being able to delay gratification has been linked to a variety of self-regulatory problems, including impulsive violence, overeating, drug abuse, unprotected sex, and unwanted pregnancies. All of these studies make an important point: Developing the beliefs and cognitive processes involved in the ability to delay gratification can influence a variety of personal behaviors and social interactions in either positive or negative ways (Francis & Susman, 2009; Peake et al., 2002).

Another cognitive process that affects personality and behavior is how much we believe in our own capabilities.

Self-Efficacy

Can I get better grades?

Students often ask about how to improve their grades. According to Albert Bandura (2004), one reason students differ in whether they receive high or low grades is related to self-efficacy.

Self-efficacy refers to the confidence in your ability to organize and execute a given course of action to solve a problem or accomplish a task.

For example, saying "I think that I am capable of getting a high grade in this course" is a sign of strong self-efficacy. You judge your self-efficacy by combining four sources of information (Bandura, 1999; E. T. Higgins & Scholer, 2008):

1. You ***use previous experiences*** of success or failure on similar tasks to estimate how you will do on a new, related task.
2. You ***compare*** your capabilities with those of others.
3. You ***listen*** to what others say about your capabilities.
4. You ***use feedback*** from your body to assess your strength, vulnerability, and capability.

You would rate yourself as having strong self-efficacy for getting good grades if you had previous success with getting high grades, if you believe you are as academically capable as others, if your friends say you are smart, and if you do not become too stressed during exams. Research shows that students' levels of self-efficacy are good predictors of their motivation and learning during college (Chemers et al., 2001; B. J. Zimmerman, 2000).

Why do my friends say that I should be getting better grades?

Influence of self-efficacy. According to Bandura's self-efficacy theory, your motivation to achieve, perform, and do well in a variety of tasks and situations is largely influenced by how strongly you believe in your own capabilities. Some people have a strong sense of self-efficacy that applies to many situations (academic settings, sports, and social interactions), others have a strong sense that applies to only a few situations (computers but not social interactions), while still others have a weak sense of self-efficacy, which predicts having less success in many of life's tasks (Eccles & Wigfield, 2002). For example, people with higher self-efficacy had greater success at stopping smoking, losing weight, overcoming a phobia, recovering from a heart attack, performing well in school, adjusting to new situations, coping with job stress, playing video games, and tolerating pain (Caprara et al., 2004; Joseph et al., 2003; Luszczynska & Sutton, 2006). These findings indicate that having either high or low self-efficacy can increase or decrease your performance and success in various tasks and personal behaviors.

Conclusion. So far we have discussed three important beliefs: whether you have an internal or external locus of control, how much you can delay gratification, and whether you have high or low self-efficacy. Research on these three beliefs supports the basic assumption of social cognitive theory—that cognitive factors influence personality development, which in turn affects performance and success in a variety of tasks and situations.

Evaluation of Social Cognitive Theory

Where does he get his courage?

Sometimes a person's experience better illustrates the power and importance of beliefs than all the research in the world. Such an experience is that of Michael J. Fox, a talented actor who has starred in popular TV shows, such as "Spin City," and movies, including the *Back to the Future* trilogy. At age 30, Michael was diagnosed with young-onset Parkinson's disease (p. 60), which began with a twitch in his left pinkie and led to relentless tremors in his arms and legs. Acting was his livelihood, but the progression of his symptoms made it increasingly difficult for him to act, even with the use of powerful medications to help control his tremors (Dudley, 2006; M. J. Fox, 2002).

The worsening of his symptoms forced Michael to make a key life decision: Would he allow his disease to lower his life's ambitions *or* would he believe in his ability to fight harder than ever before to reach his life's goals? Michael was unwilling to allow Parkinson's disease to take over his life. He began fighting against the disease and did so in incredible ways. Michael has continued to act by guest starring in television shows, such as "Boston Legal" and "Rescue Me." Also, by starting his own charitable foundation, which has become a leader in Parkinson's disease research, and speaking in favor of stem cell research, he has taken an active role in discovering a cure for Parkinson's disease.

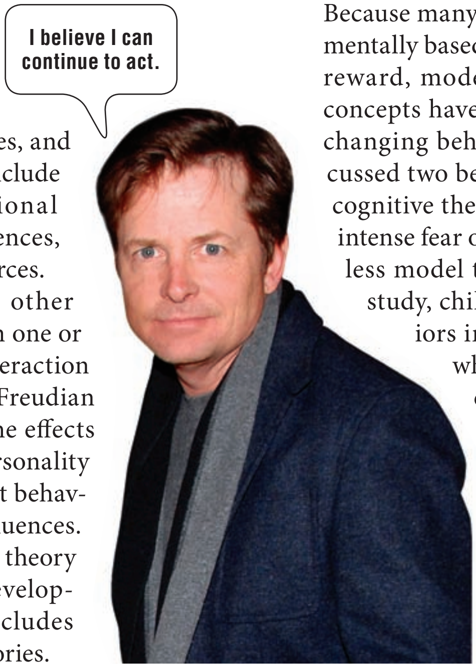
In his memoir titled *Lucky Man* (M. J. Fox, 2002), Michael speaks of the pleasure he has had in increasing public awareness of Parkinson's disease: "The ten years since my diagnosis have been the best ten years of my life, and I consider myself a lucky man." Michael's story illustrates a major assumption of social cognitive theory: Beliefs have a great influence on personality, motivation, and behavior.

We'll evaluate social cognitive theory's approach to personality development and compare it with other theories.

1 Comprehensive Approach

Social cognitive theory focuses on the interaction of three primary forces in the development of personality: cognitive-personal factors, which include beliefs, expectations, social roles, and genetic influences; behaviors, which include actions, conversations, and emotional expressions; and environmental influences, such as social, political, and cultural forces.

Bandura (2001a) points out that other theories of personality tend to focus on one or two of these factors but neglect the interaction among all three factors. For example, Freudian and humanistic theories emphasize the effects of personal and cognitive forces on personality development but neglect the significant behavioral, learning, and environmental influences. Thus, one advantage of social cognitive theory is that its approach to personality development is more comprehensive and includes more influential factors than other theories.



I believe I can continue to act.

Photo Credit: © AP Images/Charles Sykes

2 Experimentally Based

Many of the concepts used in social cognitive theory have been developed from, and based on, objective measurement, laboratory research, and experimental studies. Because social cognitive theory's concepts—such as locus of control, delay of gratification, and self-efficacy—are experimentally based, they can be manipulated, controlled, and tested and are less subject to error and bias.

In comparison, many concepts from Freudian and humanistic theories of personality were developed from clinical interviews and practice and, for that reason, these concepts (oral stage, Oedipal complex, self-actualization, positive regard) are more difficult to test and validate and more open to error and bias.

3 Programs for Change

Because many of the concepts of social cognitive theory are experimentally based and objectively defined (observational learning, self-reward, modeling behavior, self-analysis, and planning), these concepts have been used to develop very successful programs for changing behavior and personality. For example, we earlier discussed two behavioral change programs that were based on social cognitive theory. In one study, individuals who had developed an intense fear of snakes showed decreased fear after observing a fearless model touching and handling a snake (p. 225); in another study, children who had observed an adult's aggressive behaviors imitated and performed similar aggressive behaviors when given an opportunity (p. 224). These are just two examples of behavioral changes that occurred after applying concepts based on social cognitive theory (Bandura, 2001a).

4 Criticisms and Conclusions

Critics say that because social cognitive concepts focus on narrowly defined behaviors, such as self-efficacy, locus of control, and delay of gratification, social cognitive theory is a somewhat piecemeal explanation of personality development. They add that social cognitive theory needs to combine these objectively but narrowly defined concepts into a more integrated theory of personality. Finally, critics contend that social cognitive theory pays too little attention to the influence of genetic factors, emotional influences, and childhood experiences on personality development (Bouchard & Loehlin, 2001; Loehlin et al., 2003).

Despite these criticisms, social cognitive theory has had a profound impact on personality theory by emphasizing the objective measurement of concepts, the influence of cognitive processes, and the application of concepts to programs for behavioral change.

Next, we'll discuss an interesting theory of personality that emphasizes describing and assessing differences between individuals and explaining why we do not always act in a consistent way.

B. Trait Theory

Definition

Do women make better cops?

At the beginning of this module, we told you about Kiran Bedi (photo below), who in 1972 became the first female police officer in India. This was no small achievement in a country where women struggle to break free of their second-class status, which is rooted in India's ancient culture. But, even in the United States, the land of opportunity, throughout the 1970s, 1980s, and 1990s, women had to fight discrimination and harassment from male police officers who believed that women did not have the physical or mental strength to be police officers (Copeland, 1999). However, a number of studies have shown that women do make good police officers and, in situations involving domestic abuse, they are more successful than policemen because policewomen have better interpersonal skills than men (Lonsway et al., 2003).

Which traits of policewomen make them better at keeping the peace?

Peacekeeper. For example, police officer Kelly, who is female, patrols an area known for problems with street thugs. Although we may think that the best way to control thugs is with threat or force, Kelly rarely uses either. Kelly readily admits that her physical strength cannot always match that of some of the macho males she encounters. "Coming across aggressively doesn't work with gang members," Kelly explains. "If that first encounter is direct, knowledgeable, and made with authority, they respond. It takes a few more words but it works" (McDowell, 1992, p. 70). As another woman police officer said, "We've been learning our whole lives how to deal with things without having to resort to physical strength and physical violence" (Munoz, 2003, p. B2). These examples suggest that, in some situations, women make better and more effective cops than men because they have different personality traits.

Men. Traits of male officers include being assertive, aggressive, and direct, which help them act as enforcers.

Women. Traits of female officers include being compassionate, sympathetic, and diplomatic, which help them act as peacekeepers.

The reason female police officers act more as peacekeepers and male police officers act more as enforcers may be explained by trait theory.

Trait theory is an approach for analyzing the structure of personality by measuring, identifying, and classifying similarities and differences in personality characteristics or traits.

The basic unit for measuring personality characteristics is the trait.

A ***trait*** is a relatively stable and enduring tendency to behave in a particular way.

For example, traits of female police officers include being compassionate, sympathetic, and diplomatic, which help them function as peacekeepers, while traits of male police officers include being assertive, aggressive, and direct, which help them function as enforcers. Determining exactly how many traits are needed to describe someone's personality took psychologists almost 60 years.

Identifying Traits

How to describe these five persons?

How would you describe the personalities of a criminal, clown, graduate, nun, and beauty queen? This seemingly impossible task was the major goal of personality researchers. They were determined to find a list of traits whose two characteristics seemed mutually exclusive: The list had to contain very few traits but at the same time be able to describe differences among anyone's and everyone's personality, from avocado grower to zookeeper. The search for this elusive list began in the 1930s with, of all things, a dictionary.

Which . . .

How many traits can there be?

In the 1930s, Gordon Allport and an associate went through the dictionary and selected every term that could distinguish differences among personalities (Allport & Odbert, 1936). They found about 18,000 terms that dealt with all kinds of personality differences; of these, about 4,500 were considered to fit their definition of personality traits. Allport defined ***traits*** as stable and consistent tendencies in how an individual adjusts to his or her environment. The advantage of Allport's list was that it was comprehensive enough to describe anyone's and everyone's personality. The disadvantage was that it was incredibly long and thus impractical to use in research.

. . . five . . .

. . . traits . . .

Allport's search for a list of defining traits set the stage for future research. However, his list of thousands of traits needed to be organized into far fewer basic traits. This task fell to Raymond Cattell.

. . . describe . . .

Aren't some traits related?

In the 1940s, Raymond Cattell (1943) took Allport's list of 4,500 traits and used factor analysis to reduce the list to the most basic traits.

Factor analysis is a complicated statistical method that finds relationships among many different or diverse items and allows them to be grouped together.

. . . each of these five different personalities?

Cattell used factor analysis to search for *relationships* among hundreds of traits on Allport's list so that the original list could be reduced to 35 basic traits, which Cattell called ***source traits.*** He claimed that these 35 basic traits could describe all differences among personalities. Although Cattell's achievement was remarkable, his list of 35 traits—and even his further reduction of the list to 16 traits—still proved too long to be practical for research and only moderately useful in assessing personality differences. Obviously, Cattell's list needed more reducing, but that was to take another 30 years.

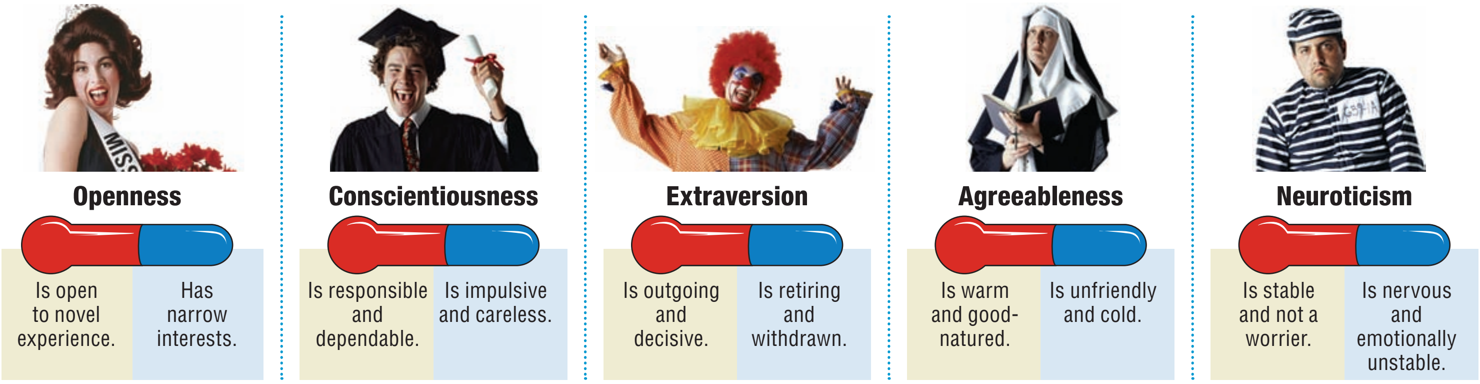
Finding Traits: Big Five

Can it be done with just five?

From the 1960s to the early 1990s, about a dozen researchers in several countries were using factor analysis to find relationships among lists of adjectives that described personality differences. Doing the impossible, researchers reduced the list of 35 traits to only 5, which make up the five-factor model of personality (Burger, 2008; Durrett & Trull, 2005).

The ***five-factor model*** organizes personality traits and describes differences in personality using five categories, which are ***openness, conscientiousness, extraversion, agreeableness,*** and ***neuroticism.***

These five factors became known as the ***Big Five*** and are easy to remember if you note that their first letters make the acronym OCEAN. Each of the five factors actually represents a continuum of behavior, as briefly described in the figure below.



Openness
Is open to novel experience.
Has narrow interests.
Conscientiousness
Is responsible and dependable.
Is impulsive and careless.
Extraversion
Is outgoing and decisive.
Is retiring and withdrawn.
Agreeableness
Is warm and good-natured.
Is unfriendly and cold.
Neuroticism
Is stable and not a worrier.
Is nervous and emotionally unstable.

Hot and cold. You can think of each Big Five factor as a ***supertrait*** because each factor's thermometer includes dozens of related traits at the hot and cold ends. For example, conscientiousness, at the hot end, includes the traits of being dependable, responsible, deliberate, hardworking, and precise; at the cold end are the traits of being impulsive, careless, late, lazy, and aimless. Although it took 30 years of research, coming up with the Big Five means that trait theory finally achieved its major goal, which was to describe and organize personality characteristics using the fewest number of traits (R. R. McCrae & Costa, 2003).

Importance of the Big Five

Unlike earlier attempts to identify traits, there is now convincing evidence that the Big Five, or five-factor theory, can indeed describe personality differences among many thousands of individuals by using only five categories or traits.

Big question. The five-factor model has been replicated in many different countries, which led researchers to ask if the structure of personality was shaped primarily by different ***cultural factors*** (child-rearing practices, religious and moral values, language similarities) or primarily by differences in the ***basic human ways*** of acting and experiencing that are universal, or similar across all peoples and countries.

OCEAN

Each letter in the word OCEAN is the first letter of one of the Big Five traits.

Because support for the five-factor model was found in many very different countries or cultures, researchers concluded that the basic structure of human personality arises from some universal living experience or biological basis rather than being shaped by individual countries or cultures (Jang et al., 2006; R. R. McCrae & Costa, 2003; Yamagata et al., 2006). If basic human personality structure is universal, it means that the personalities of individuals in different countries can be described by using the Big Five traits.

Big Five in the Real World

Because personality similarities and differences can be described by five categories, questionnaires based on the five-factor theory can more accurately assess personality, which is one of the major tasks of therapists and psychologists.

For instance, the Big Five traits can be used to describe differences between male and female police officers. Compared with policemen, policewomen are generally more agreeable (sympathetic, friendly, helpful), more open (insightful, intelligent), and more extraverted (sociable, talkative). These kinds of traits result in policewomen being less authoritarian, more diplomatic, and better at defusing potentially dangerous situations (Spillar & Harrington, 2000).

Also, questionnaires based on the five-factor theory reveal differences among people in the United States and in other countries. The Swiss, for instance, rate themselves as highly conscientious, while Canadians and Indians rate themselves as highly agreeable (R. McCrae, 2008). In the United States, people in the Midwest and Southeast score highest in agreeableness, people in the South and Midwest score highest in conscientiousness, and people in the Northeast and West score highest in openness (Rentfrow et al., 2008).

Researchers generally agree the five-factor theory is a leap forward in trait theory and is useful in defining personality structures and differences, predicting behaviors, and identifying personality problems (Burger, 2008; R. R. McCrae & Costa, 2003). A new research focus is to explore the possible existence of the "Big One," or General Factor of Personality (Musek, 2007; Rushton & Irwing, 2008). The Big One is being compared to Spearman's factor ***g*** in the area of intelligence (p. 282). In the years ahead, we'll learn more about whether such a general factor of personality exists.

Although each of us possesses at least five relatively enduring supertraits that push us to behave in a stable way, why do we sometimes contradict ourselves and behave differently in different situations?

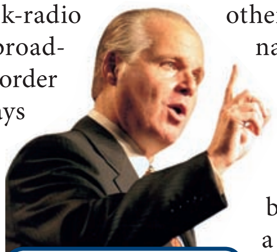
B. Trait Theory

Person Versus Situation

How does private life compare to public life?

The best-known right-wing talk-radio host is Rush Limbaugh, who broadcasts his conservative law-and-order views to 20 million fans five days a week. For example, when Grateful Dead guitarist Jerry Garcia died in 1995, Limbaugh said, "When you strip it all away, Jerry Garcia destroyed his life on drugs. And yet he's being honored, like some godlike figure. Our priorities are out of whack, folks" (Laurence, 2003, p. F7). Talking about drug users, Limbaugh said, ". . . too many whites are getting away with drug use . . . The answer is to go out and find the ones who are getting away with it, convict them and send them up the river, too" (Laurence, 2003, p. F7).



Limbaugh preached law and order in public but in private he was a drug addict.

Then, on October, 16, 2003, the *National Enquirer* headline read, "Rush Limbaugh Caught in a Drug Ring." According to several other respected news accounts, Limbaugh had become a narcotic addict (pain pills). His maid claimed that for three years she had bought enough "baby blues" (OxyContin® pills) to "kill an elephant." According to police, Limbaugh obtained 2,000 pain pills during only a six-month period. Limbaugh admitted to being a drug addict, turned himself in, and went into a drug rehab program (Campo-Flores & Thomas, 2006; E. Thomas, 2003).

The observation that, like Rush Limbaugh, individuals often behave differently in different situations questions one of the basic assumptions of trait theory, which is that traits create tendencies to behave in certain consistent ways. Psychologist Walter Mischel (1968) was one of the first to conduct a series of classic experiments on why traits fail to predict the behavior of people across different situations.

Experiment: Person-Situation

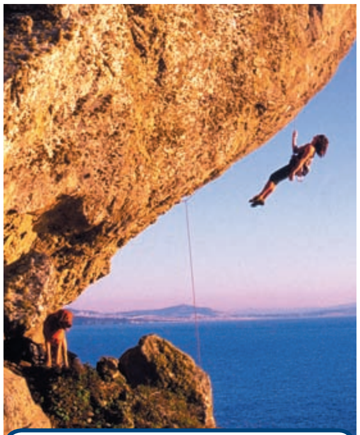
To test trait theory's basic assumption that people behave consistently across situations, Walter Mischel and Philip Peake (1982) asked college students, "How conscientious are you?" If students answer that they are "very conscientious," trait theory predicts that they will behave conscientiously in many different situations. Mischel then observed how conscientious college students behaved across 19 very different situations, such as attending classes, getting homework in on time, and keeping their rooms neat.

Students who rated themselves as very conscientious behaved that way day after day in similar situations. However, these same students did not behave conscientiously across all 19 conditions. For example, very conscientious students might clean their rooms daily but not get their homework in on time, or they might attend all their classes but not clean their rooms. Researchers concluded that, as trait theory predicted, students behaved with great consistency in the ***same*** situation, but contrary to trait theory's prediction, students behaved ***differently*** or with low consistency across different situations. This finding led to what is now called the person-situation interaction.

The ***person-situation interaction*** means that a person's behavior results from an interaction between his or her traits and the effects of being in or responding to cues from a particular situation.

The person-situation interaction explains that even if you were an extravert, you would behave differently at a wedding than at a funeral because each of these situations creates different cues to which you respond (Mischel & Shoda, 1995). Similarly, the person-situation interaction describes how Rush Limbaugh could be righteous in criticizing Jerry Garcia's drug use while being a drug addict himself.

The person-situation interaction says that to understand or predict a person's behavior across situations, we must consider both the person's traits and the powerful cues that come from being in each different situation (Funder, 2008).



If you are open to new experiences, would you try this? Do you see the dog?

Conclusions

There is no question that humans have stable and consistent parts of their personalities, which are called traits. There is no question that personality differences can be accurately described by using the Big Five traits. However, people may act inconsistently or contradictorily because traits interact with and are partly dependent upon situational cues. Thus, even though you consider yourself open to new experiences, you might very well draw the line and say "NO!" to potentially dangerous rock climbing (below left photo). Although researchers have found that traits are not consistent across all situations, the concept of traits is still useful for two reasons (G. Matthews et al., 2003).

Descriptions. First, traits are useful because they provide a kind of shorthand method for describing someone's personality. In fact, if we asked you to describe your best friend, you would essentially list this person's traits.

Predictions. Second, traits are useful because they help predict someone's behavior in future situations. However, you must keep in mind the person-situation interaction, which means you must take into account how the person's traits will interact with the situation's cues. For example, my friends would predict that I (R. P.) generally try to watch my weight, but they also know that when placed in front of a dessert counter, I can easily consume my weight in chocolate. However, researchers found it is possible to significantly increase the accuracy of predicting a person's behaviors across situations if that person is actually observed in a number of different settings (G. Matthews et al., 2003).

Conclusion. Most personality researchers agree that traits, such as the Big Five, are useful in describing our stable and consistent behavioral tendencies, yet they warn that traits may not predict behaviors across different situations (Funder, 2008; G. Matthews et al., 2003).

Does saying that traits are stable and consistent mean that one's personality gradually becomes fixed?

Photo Credits: top, © AP Images/Joseph Kaczmarek; bottom, © Galen Rowell/Corbis

Stability Versus Change

How changeable are your traits?

If you are now 16, 18, 20, 25, or 30, what will your personality be like when you're 40, 50, 60, 70, or 80? The question of how much your personality traits remain the same and how much they change is answered by using a research approach called the longitudinal method.

Longitudinal method **means that the same group of individuals is studied repeatedly at many different points in time.**

For example, if you asked your parents to list your personality traits at age 3, would these traits match your traits at age 21? In other words, how changeable or fixed are your personality traits?

3 to 21 Years Old

Will this 3-year-old child's personality traits . . .

To answer the question of how much personality traits change or remain the same, researchers did a longitudinal study on 1,000 children, whose traits were assessed at age 3 and then reassessed when the same children were 21 years old. Based on their assessment, the personality traits of 3-year-old children were divided into five different personality groups that were labeled undercontrolled, inhibited, confident, reserved, and well-adjusted (Caspi, 2000).

. . . be similar to those he has at 21 years old?

Consistency. Researchers found significant consistencies between traits assessed at 3 years and at 21 years old. For example, traits of 3-year-old children in the ***under-controlled group*** included being impulsive, restless, and distractible. When these 3-year-old children were retested at age 21, their traits were similar and included being reckless, careless, and favoring dangerous and exciting activities. In comparison, traits of 3-year-old children in the ***well-adjusted group*** included being confident, having self-control, and easily adjusting to new or stressful situations. When these 3-year-old children were retested at age 21, their traits were similar and included being in control, self-confident, and all-around well-adjusted and normal adults. Researchers concluded that the origin or development of a person's more stable personality traits begins around age 3. This means that traits observed at age 3 predict personality traits observed later in the same young adults (Caspi, 2000).

Change. Although there were remarkable consistencies in personality traits between age 3 and age 21, researchers point out that there are often major changes in emotional traits during adolescence. During adolescence, individuals may become less responsible, less cautious, and more moody or impulsive (Caspi & Roberts, 1999).

What happens to personality development after age 21, and does personality ever stop changing?

22 to 80 Years Old

If you are 20, 25, or 30, what will your personality be like at 60, 70, or 80? Answers come from longitudinal studies, which reached the following conclusions (Caspi et al., 2005; R. R. McCrae & Costa, 1999; R. R. McCrae et al., 2000; Roberts et al., 2006; Terracciano et al., 2006; Trzesniewski et al., 2003):

Before age 30, personality may go through major changes, but . . .

1 Major changes in personality occur during childhood, adolescence, and young adulthood. Between 22 and 30, both men and women become less emotional, less likely to be thrill seekers, and somewhat more likely to be cooperative and self-disciplined. These personality changes are often associated with becoming more mature.

2 In fact, longitudinal studies find that most major changes in personality occur before the age of 30 because adolescents and young adults are more willing to adopt new values and attitudes or revise old ones.

3 Personality traits are relatively fixed by age 30, after which changes in personality are few and small. However, after 30, adults continue to grow in their ideas, beliefs, and attitudes as they respond to changing situations and environments. For example, an eager tennis player may, with age, become an eager gardener, but an eager liberal is unlikely to become an eager conservative.

4 Men and women, healthy and sick people, and Blacks and Whites all show the same stable personality pattern after age 30. Because personality is stable, it is somewhat predictable. However, individuals may struggle to overcome or change certain traits (become less shy or more confident), which brings up the question of how much personality changes during adulthood.

5 When middle-aged and older adults were asked to describe the course of their personality development, they all described increases in desirable traits (energetic, realistic, intelligent) as they grew older. But on objective tests, these same individuals showed little or no change in these same traits. These findings indicate that as people grow older, they tend to report more socially desirable or stereotypical responses rather than what actually has occurred.

Conclusions. Your personality is more likely to change the younger you are, but after age 30, personality traits are relatively stable and fixed. However, depending upon situations, stressors, and challenges, some change can occur throughout adulthood (Kluger, 2006a). Thus, personality has the interesting distinction of being both stable and changeable (up to a point). One reason personality traits remain relatively stable across time is that they are influenced by genetic factors, which we'll discuss next.

. . . after age 30, personality is relatively fixed and difficult to change.

C. Genetic Influences on Traits

PowerStudy 4.5™

Module 4
A. Genes & Evolution

Behavioral Genetics

Why are twins so similar?

Jim Lewis (left photo) and Jim Springer (right photo) drove the same model blue Chevrolet, smoked the same brand of cigarettes, owned dogs named Toy, held jobs as deputy sheriff, enjoyed the same woodworking hobby, and had vacationed on the same beach in Florida. When they were given personality tests, they scored almost alike on traits of flexibility, self-control, and sociability. The two Jims are identical twins who were separated four weeks after birth and reared separately. When reunited at age 39, they were flabbergasted at how many things they had in common (Leo, 1987).

Why did they drive the same kind of car, smoke the same cigarettes, hold the same kind of job, and both name their dogs Toy?

These surprising coincidences come from an ongoing University of Minnesota project on genetic factors (Bouchard, 1994; Bouchard & Loehlin, 2001). One of the project's major questions is whether the similarities between the two Jims are simply coincidence or reflect the influence of genetic factors on personality traits.

Most of us grew up hearing one or both of these phrases: "You're acting just like your father" or "You're behaving just like your mother." These phrases suggest that genetic factors we inherit from our parents influence our behaviors. Psychologists have only recently recognized the importance and influence of genetic factors, which have resulted in a new area called behavioral genetics.

Behavioral genetics **is the study of how inherited or genetic factors influence and interact with psychological factors to shape our personality, intelligence, emotions, and motivation and also how we behave, adapt, and adjust to our environments.**

Many of us have a difficult time accepting the idea of genetic influences because we equate genetic with *fixed*. However, genetic factors do not fix behaviors but establish a range for a behavior, which environmental factors foster or impede. For example, a girl born with genes for shyness whose parents appropriately encourage her to socialize and interact with other children is more likely to outgrow her shyness than a girl whose parents simply believe the inherited genes for shyness indicate she will remain shy and therefore do not encourage her to interact with others (Begley, 2008d).

As we discuss studies showing that genetic factors influence and set a range for development of various personality traits, please remember that our actual traits result from the interaction between genetic factors and environmental influences.

Studying Genetic Influences

What's in the genes?

Few studies have made as great an impact on beliefs about what shapes personality and behavior as the twin study at the University of Minnesota. Until the early 1990s, most psychologists recognized that genetic factors shaped personality but believed that genetic factors had much less impact than environmental factors. Then in 1990, Thomas Bouchard and his colleagues (1990) published results of the first study to simultaneously compare four different groups of twins: identical twins reared together, identical twins reared apart, fraternal twins reared together, and fraternal twins reared apart. Remember that identical twins share nearly 100% of their genes, while fraternal twins share only 50% of their genes and thus are no more genetically alike than ordinary brothers and sisters. This study allowed researchers to separate genetic factors (identical versus fraternal twins) and environmental factors (reared together versus reared apart).

We're identical twins, and we share nearly 100% of our genes.

This is a piece of the genetic code, which uses a chemical alphabet to write instructions that influence the development of personality traits.

More than 100 sets of twins in the United States, Great Britain, and many other countries participated in this initial study. Each participant was given over 50 hours of medical and psychological assessment, including four different tests to measure personality traits. Those identical and fraternal twins who were reared apart were adopted shortly after birth and had not met their twin until this study brought them together for testing. The measure that researchers use to estimate genetic influences is called heritability.

Heritability **is a statistical measure that estimates how much of some cognitive, personality, or behavioral trait is influenced by genetic factors.**

We're fraternal twins, and we share only 50% of our genes.

Heritability is expressed on an increasing scale of influence from 0.0 to 1.0. That is, if genetic factors have no influence, the heritability is 0.0, having half the influence is indicated by 0.5, and having total control over behavior is indicated by 1.0. For example, heritability of IQ is about 50% (p. 292), which means that about 50% of an individual's IQ score is explained by genetic factors; heritability of mental disorders is about 40–70% (pp. 533–539); and, as we'll discuss next, heritability estimates for personality traits are about 40–50%. However, keep in mind that genetic factors interact with environmental factors, which explain about 40–60% of the development of IQs, mental disorders, and personality traits.

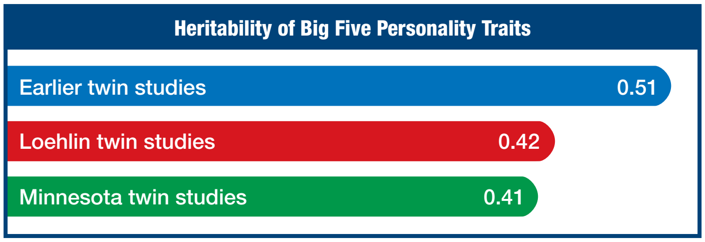
Data from Twin Studies

Do genes influence the Big Five?

Identical twins Jim Lewis and Jim Springer (photos opposite page) were subjects in the now famous Minnesota twin study. Their scores were similar on personality tests that measured the Big Five traits—openness, conscientiousness, extraversion, agreeableness, and neuroticism. (Note that by taking the first letter of each Big Five trait, you make the word OCEAN.) One reason the two Jims' scores on personality tests were so similar was that their genetic factors were identical.

OCEAN

There are now many studies on thousands of twins, both identical and fraternal, who were reared together and apart and whose data were analyzed by different groups of researchers. Results from earlier studies and two large and recent studies are shown in the graph below (Bouchard & Loehlin, 2001). Researchers estimate the heritability of personality traits ranges from 0.41 to about 0.51, which means that genetic factors contribute about 40–50% to the development of an individual's personality traits (Bouchard, 2004).



Even though genetic factors are responsible for about half of each of the Big Five personality traits we develop, that still leaves about half coming from environmental factors. We'll describe two kinds of environmental factors—shared and nonshared—that influence personality development.

Influences on Personality

What shapes personality?

As I (R.P.) was growing up, I remember hearing my parents talking (when they thought I wasn't listening) about how different I was from my older brother and sister. My parents questioned how my brother and sister and I could be so (very) different even though we had the same parents, lived in the same house in the same town, and even went to the same school and church. One reason that brothers and sisters develop such different personalities is that 50% of their genes are different (and 50% are shared). And another important reason that brothers and sisters develop different personalities is that each brother's or sister's unique set of genetic factors interacts differently with his or her environment. Researchers have broken down the contributions to personality development into the following four factors.

40% Genetic Factors

The fingerprints of the two Jims were almost identical because they shared nearly 100% of their genes, and genetic factors contribute 97% to the development of ridges on fingertips (Bouchard et al., 1990). In comparison, the two Jims' scores were similar but not identical on personality traits of self-control, flexibility, and sociability because, although they share almost 100% of their genes, genetic factors contribute about 40–50% to the kind of personality traits they developed. While genetic factors contribute about half to the development of certain personality traits, the next biggest factor is something of a surprise.

27% Nonshared Environmental Factors

Although we know that the two Jims showed remarkable similarities in personality, they also displayed unique differences. Jim Lewis (left photo) says that he is more easygoing and less of a worrier than his identical twin, Jim Springer (right photo). When the twins get on a plane, Jim Springer worries about the plane being late, while Jim Lewis says that there is no use worrying (*San Diego Tribune,* November 12, 1987). One of the reasons that the two Jims developed different personality traits is that about 27% of the influence on personality development comes from how each individual's genetic factors react and adjust to his or her own environment. These factors are called ***nonshared environmental factors*** because they involve how each individual's genetic factors react and adjust to his or her particular environment.

26% Error

About 26% of the influence on personality development cannot as yet be identified and is attributed to errors in testing and measurement procedures. As methodology improves, this error percentage will decrease and other factors will increase.

7% Shared Environmental Factors

About 7% of the influence on personality development comes from environmental factors that involve parental patterns and shared family experiences. These factors are called ***shared environmental factors*** because they involve how family members interact and share experiences. One of the major surprises to come out of the twin studies was how little impact parental practices and shared family experiences have on personality development. Researchers concluded that being raised in the same family contributes little (about 7%) to personality development. Far more important for personality development are nonshared environmental factors (27%), which refer to how each child's unique genetic factors react and adjust to being in that family (Bouchard & Loehlin, 2001; De Fruyt et al., 2006). You can think of genetic factors as pushing and pulling personality development in certain directions, while environmental factors join in to push and pull it in the same or different directions.

Next, we'll take a last look at the impact of trait theory.

D. Evaluation of Trait Theory

Could we live without traits?

It would be very difficult to live without traits because you use them constantly, usually without knowing it. For example, whenever you describe someone or predict how he or she will behave, your descriptions of personality and predictions of behaviors are based almost entirely on knowing the person's traits. Newspapers are full of personal ads, which are essentially a list of most-desired traits.

Personal Want Ad

Personal ads are based on traits.

Although traits are very useful as a shorthand to describe a person's personality and predict a person's behaviors, critics raise three major questions about traits: How good is the list? Can traits predict? What influences traits? We'll discuss each issue in turn.

How Good Is the List?

The Big Five, or five-factor trait theory, assumes that all similarities and differences among personalities can be described by an amazingly short but comprehensive list of five traits—openness, conscientiousness, extraversion, agreeableness, and neuroticism (OCEAN). Each of the ***Big Five traits*** has two poles or two dimensions, which include dozens of related traits. The Big Five traits' ability to describe personality has now been verified in many different countries, with different populations and age groups (Allik & McCrae, 2004; Schmitt et al., 2007).

The Big Five traits have the ability to describe personalities of children and adults in many different countries.

Critics of the five-factor model point out that the data for the model came from questionnaires that may be too structured to give real and complete portraits of personalities. As a result, data from questionnaires may paint too simplistic a picture of human personality and may not reflect its depth and complexity (J. Block, 1995). Critics also point out that traits primarily describe a person's personality rather than explain or point out its causes (Digman, 1997).

In defense of the five-factor theory, researchers have shown that the Big Five traits provide a valid and reliable way to describe personality differences and consistencies in our own lives and in our social interactions with others (R. R. McCrae & Costa, 2003).

Can Traits Predict?

One of the more serious problems faced by early trait theory involved the assumption that, since traits are consistent and stable influences on our behaviors, traits should be very useful in predicting behaviors.

Rush Limbaugh preached law and order on his talk-radio show but was a drug addict in private.

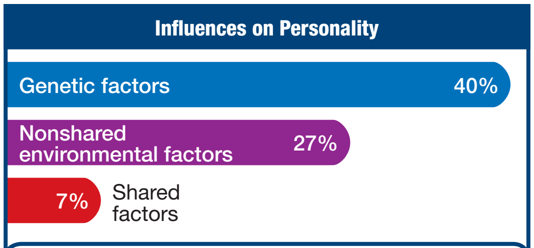
But how does trait theory explain why Rush Limbaugh behaved so inconsistently? He preached law and order and right-wing conservative moral standards on his radio talk show, but in his private life he had become a drug addict and was allegedly having his maid buy drugs on the black market.

One explanation is that Limbaugh did behave in a consistent moral way in public situations (radio talk shows). However, in other situations, such as his private life, he had become a drug addict. This problem of predicting behavior across situations is known as the ***person-situation interaction.*** Researchers found that situations may have as much influence on behavior as traits do, so situational influences must be taken into account when predicting someone's behavior (Funder, 2008). Researchers found that traits could better predict behaviors if traits were measured under different conditions and situations.

Currently, the Big Five traits are considered useful concepts for describing consistent and stable behavioral tendencies in similar situations, but traits do not necessarily predict behaviors across different situations.

What Influences Traits?

One major surprise from twin studies was what relatively little effect parental practices or shared family experiences have on personality development (graph below). Researchers concluded that parental practices or ***shared factors*** contributed only about 7% to personality development. In contrast, how each child personally reacts or adjusts to parental or family practices, called ***nonshared factors,*** contributed about 27% to personality development (Bouchard & Loehlin, 2001; Plomin & Crabbe, 2000). This finding questioned a major belief of developmental psychologists, who hold that sharing parental or family environment greatly influences personality development among siblings (brothers and sisters). Instead, twin research suggests that psychologists need to look more closely at each child's reactions to his or her family environment as a major influence on personality development.



Personality development depends more on genetic and nonshared factors (child's individual reactions) than on shared parental influences.

According to behavioral geneticists, the idea of genes influencing complex human behaviors was unthinkable as recently as 15 years ago. Today, however, there is convincing evidence that genetic factors exert a considerable influence on many complex human behaviors, including intelligence, mental health, and personality traits (Bouchard, 2004). Yet these same researchers warn that ***genetic influences*** on human behavior should not be blown out of proportion. Because heritability scores generally do not exceed 50%, this means the remaining 50% or more involves ***environmental influences,*** especially nonshared environmental influences.

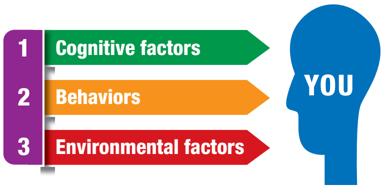
Figure/Text Credit: Bar graph data from "Genes, Environment, and Personality," by T. J. Bouchard, 1994, *Science, 264,* 1700–1701. American Association for the Advancement of Science. Additional data from Bouchard & Loehlin, 2001, Plomin & Crabbe, 2000.

Concept Review

1. Social cognitive theory says that personality development is primarily shaped by three interacting forces: __________, __________, and __________.



2. The above three forces all interact to influence how we evaluate, interpret, and organize __________ and apply such knowledge to ourselves and others.

3. An example of the social cognitive approach is Bandura's social cognitive theory, which says that personality development, growth, and change are influenced by four distinctively human cognitive processes: highly developed (a) __________ ability, (b) __________ learning, (c) __________ behavior, and (d) __________.

4. Three different beliefs based on social cognitive theory have been shown to influence personality development and behavior. Rotter referred to beliefs concerning how much control we have over situations or rewards. If we believe that we have control over situations and rewards, we are said to have an (a) __________. If we believe that we do not have control over situations and rewards and that events outside ourselves (fate) determine what happens, we are said to have an (b) __________.

Should I take one marshmallow now or wait and get two later?

5. According to Bandura, our personal beliefs regarding how capable we are of exercising control over events in our lives—for example, carrying out certain tasks and behaviors—is called (a) __________, which, in turn, affects our performance on a wide variety of behaviors. Mischel devised ways of measuring our ability to voluntarily postpone an immediate reward and persist in completing a task for the promise of a future reward, which is called (b) __________.

6. The approach to describe the structure of personality that is based on identifying and analyzing ways in which personalities differ is known as __________ theory.

7. A relatively stable and enduring tendency to behave in a particular way is called a (a) __________. A statistical procedure that may be used to find relationships among many different or diverse items, such as traits, and form them into selected groups is called (b) __________.

8. The model that organizes all personality traits into five categories that can be used to describe differences in personality is called the (a) __________ model. This model uses the Big Five traits, which are (b) __________, __________, __________, __________, and __________.

9. Research supports the five-factor model and the Big Five traits. Each of the Big Five traits has two poles or dimensions and represents a wide range of __________.

10. Walter Mischel said that to predict a person's behavior we must take into account not only the person's traits but also the effects of the situation; this became known as the (a) __________. According to this idea, a person's behavior results from an (b) __________ between his or her traits and the effects of being in a particular situation.

11. To investigate whether personality changes as people grow older, psychologists study the same individuals at different times; this is called a (a) __________ study. In general, studies have shown that personality is more likely to change if a person is under (b) __________ years old. After that, changes usually involve variations on the same behavioral theme or accompany changes in social roles.

12. The field that focuses on how inherited or genetic factors influence and interact with psychological factors is called (a) __________. A statistical measure that estimates how much of some behavior is due to genetic influences is called (b) __________.

13. Studies have found that about 40% of the influence on personality development comes from (a) __________; about 27% comes from how each person adjusts to his or her own environment, which is called (b) __________; and about 7% comes from parental patterns and family experiences, which are called (c) __________.

Answers: *1. cognitive-personal factors, behavior, environmental influences; 2. information; 3. (a) language, (b) observational, (c) purposeful, (d) self-analysis; 4. (a) internal locus of control, (b) external locus of control; 5. (a) self-efficacy, (b) delay of gratification; 6. trait; 7. (a) trait, (b) factor analysis; 8. (a) five-factor, (b) openness, conscientiousness, extraversion, agreeableness, neuroticism; 9. behaviors; 10. (a) person-situation interaction, (b) interaction; 11. (a) longitudinal, (b) 30; 12. (a) behavioral genetics, (b) heritability; 13. (a) genetic factors, (b) nonshared environmental factors, (c) shared environmental factors*

E. Research Focus: 180-Degree Change

Total Change in One Day?

What triggers a major change?

Sometimes researchers study unusual behaviors that seem to contradict what is known. For example, anyone who has ever tried to change some behavior finds it difficult because traits are relatively stable and enduring. For this reason, it's difficult to believe people who claim to have totally changed their personalities in minutes, hours, or a single day. Researchers call these sudden, dramatic changes quantum personality changes (W. R. Miller & C'de Baca, 1994, 2001).

A ***quantum personality change*** refers to making a very radical or dramatic shift in one's personality, beliefs, or values in minutes, hours, or a day.

How much could you change in one day?

For example, here's the quantum personality change of Bill Wilson, who cofounded Alcoholics Anonymous (AA). He was in the depths of alcoholic despair and depression when he suddenly saw his room lit with a bright light. In his mind's eye, he saw himself on a mountaintop and felt that spirit winds were blowing through him. Then, suddenly, a simple but powerful thought burst upon him: he was a free man (E. Kurtz, 1979). This dramatic experience changed Wilson's personality 180 degrees as he went from being a desperate and hopeless drunk to being a sober and dedicated worker who devoted his life to helping others overcome alcoholism.

Reports of sudden and major changes in personality challenge two well-established findings: First, personality traits are stable and enduring tendencies that may change gradually but rarely undergo sudden and dramatic changes; and second, even when people want to change their personalities, as in therapy, it doesn't happen overnight but takes considerable time and effort. Then how can quantum personality changes occur, often in a single day? To answer this question, researchers first had to develop a method to study quantum changes.

Method

Researchers found people who had experienced a quantum personality change through a feature story in the local paper (Albuquerque, New Mexico). Researchers asked for volunteers who, in a relatively short period of time, had experienced a transformation in their basic values, feelings, attitudes, or actions. Out of a total of 89 people who responded, 55 were found acceptable. These 55 subjects were given a series of personality tests and structured interviews (average length 107 minutes).

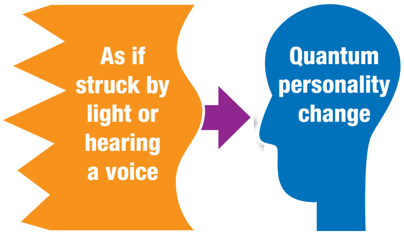
Structured interviews involve asking each individual the same set of relatively narrow and focused questions so that the same information is obtained from everyone.

During structured interviews, all subjects were asked the same detailed questions about the what, when, and where of the unusual experiences that had apparently transformed their personalities so completely.

Structured interviews use the subjects' self-reports to provide information about subjective thoughts, feelings, and experiences, which are most often unobservable cognitive and emotional processes.

Results

Researchers used a variety of personality tests to make sure the subjects (31 women and 24 men) performed within the normal range on personality tests and had no strange problems. In fact, based on the battery of personality tests and interviews, all the subjects seemed to be normal, ordinary individuals who had had extraordinary experiences (W. R. Miller & C'de Baca, 1994). Here are some of the study's major findings:



As if struck by light or hearing a voice
Quantum personality change

- A majority of subjects (58%) could specify the date and time of day when the quantum experience occurred even though the experience had occurred, on average, 11 years earlier.
- A majority of subjects (75%) reported that the quantum experience began suddenly and took them by surprise. For some the experience lasted only minutes (13%), and for most it was over within 24 hours (64%). The actual experiences included being struck by an intense thought, making a total commitment, hearing a voice, and hearing God's voice.
- A majority of subjects (56%) reported a high level of emotional distress and a relatively high level of negative life experiences in the year before the quantum experience.
- Most (96%) reported that the quantum experience had made their lives better, and most (80%) stated that the changes had lasted.

All of these 55 individuals reported that they had, in a single day or less, experienced a 180-degree change in personality. For the vast majority, the quantum change in personality seems to have resulted from or been triggered by a period of bad times. After the quantum change, subjects reported that their lives had improved.

When these individuals were interviewed ten years later, researchers found that the dramatic changes continued and no one reported returning to their old ways (C'de Baca & Wilbourne, 2004).

Conclusions

The quantum personality changes reported by the subjects were dramatically larger than are ordinarily observed, occurred in a shorter period of time than is normally reported, and lasted for years (C'de Baca & Wilbourne, 2004; W. R. Miller & C'de Baca, 1994).

For most of the subjects, the changes represented an increased sense of meaning, happiness, and satisfaction; some reported a sense of closeness to God. This study suggests that quantum changes in personality do occur and may be one way a person solves some long-standing and stressful personal problem.

In many cases, people who experienced quantum personality changes also reported subsequent changes in behavior.

As you'll see next, how much personality influences behavior is partly dependent on one's culture.

F. Cultural Diversity: Suicide Bombers

Why was Arien the exception?

One of the most difficult and tragic issues for Westerners to understand is the reasons behind suicide bombers. Recently, a young woman agreed to tell her story of how she became a suicide bomber (Bennet, 2002).

I believe Israeli forces killed my fiancé and I want to avenge his death.

Arien Ahmed (right photo) was a 20-year-old Palestinian student of business administration at Bethlehem University. Five days after she had volunteered to become a suicide bomber, she was pulled out of a marketing lecture and shown how to trigger a bomb inside a backpack. She got into a old car with another would-be killer and went on her mission dressed as an Israeli woman. As she walked through an Israeli town carrying a heavy backpack containing a bomb surrounded with nails, she began to have second thoughts. She described a kind of awakening and remembered a childhood belief "that nobody has the right to stop anybody's life." At that moment she decided not to go through with the bombing. She was later arrested by Israeli police (Bennet, 2002). Arien was a rare exception, since suicide bombers almost never fail to complete their deadly missions.

Cultural & Personal Reasons

After Arien was arrested, she said that she agreed to tell her story to discourage other Palestinians from becoming suicide bombers and to gain sympathy for herself. The Israeli Security Agency, which allowed Arien to be interviewed by newspaper reporters, appeared eager to show how easily militants manipulate susceptible people and send them to kill and die (Bennet, 2002).

What conditions lead to suicide attacks? In the mid-1990s, there were more than 20 suicide attacks throughout Turkey. The attacks have since stopped because the Turkish government undertook steps to satisfy the rebel forces' demands. Since 1990, Chechnyans have engaged in suicide attacks in their effort to win their independence from Russia (Zakaria, 2003). Since 2002, Palestinian women have become increasingly involved in acts of terrorism, and nearly 100 have attempted suicide bombings (McGirk, 2007). Let's take a look at the reasons Palestinian women choose to become suicide bombers.

Since 2002, nearly 100 Palestinian women have committed suicide bombings.

What motivates a suicide bomber? Arien was motivated by both personal and cultural reasons. As she told Israeli security agents, her strong ***personal reason*** was that she wanted to avenge the death of her fiancé, whom she believed had been killed by Israeli forces (who said that her fiancé accidentally blew himself up). After his death, she said, "So I lost all my future." Arien's recruiters told her that dying as a suicide attacker would earn her the reward of rejoining her slain fiancé in paradise. Even though Arien now calls her attempt to be a suicide bomber a mistake, she said she understood it. "It's a result of the situation we live in. There are also innocent people killed on both sides" (Bennet, 2002, p. A1).

There are also strong Muslim ***cultural influences*** that encourage women, such as Arien, to become suicide bombers. For example, during the past several years, women have been increasingly involved in Palestinian terrorism largely because their involvement is unsuspected by others and their actions receive heightened media attention. The use of women as suicide bombers is also thought to convey the seriousness of the threat and to make the men involved act more aggressively (Berko & Erez, 2006; Bloom, 2005).

There are many other reasons women become suicide bombers. For instance, 21-year-old Wafa Samir al-Biss, a burn victim, volunteered to martyr herself after she was told she would never marry due to her many scars. Others become suicide bombers to escape the shame of being a rape victim. Yet others choose to become suicide bombers instead of receiving the death sentence. At least this way they believe they will die as a proud martyr (Abdul-Zahra & Murphy, 2009; Dviri, 2005; McGirk, 2007).

Jyad Sarraj, a Palestinian psychiatrist, states he cannot criticize the suicide bombers because their culture considers them to be martyrs and martyrs are considered prophets, who are revered (Sarraj, 2002). Other experts state the increasing number of women who are becoming suicide bombers shows that women are taking a step forward in achieving status equal to men (Bloom, 2005).

Do suicide bombers share certain traits? Almost all of the suicide bombers have been Muslim, relatively young, single, varying in education, with some knowledge of political causes and terror tactics (Bennet, 2002; Zakaria, 2003). These traits tend to be general, however, and apply to many Palestinians who do not become suicide bombers. Israel's national security force studied suicide bombers, and their results are puzzling. They didn't find any specific personality profile or traits that differentiated suicide bombers from nonbombers. However, as in Arien's case, some powerful, tragic emotional event, such as the death of her fiancé, may be the final hurt that, combined with cultural forces, led her to become a suicide bomber.

What does the future hold? Government officials believe that suicide attacks will continue until there is a peace settlement in the Middle East. Until then, violent Muslim groups will continue to use suicide bombers because they have widespread cultural approval and are an effective method of killing, instilling fear, and spreading their political message (Bennet, 2002).

Next, we'll briefly review the four major theories of personality to help you understand their major points.

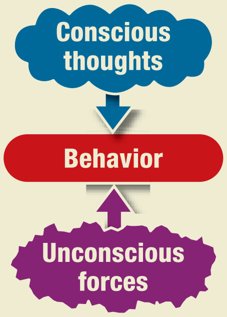
G. Four Theories of Personality

Psychodynamic Theory

Freud's psychodynamic theory, which was developed in the early 1900s, grew out of his work with patients.



Freud's ***psychodynamic theory of personality*** emphasizes the importance of early childhood experiences, the importance of repressed thoughts that we cannot voluntarily access, and the conflicts between conscious and unconscious forces that influence our thoughts and behaviors. (Freud used the term *dynamic* to refer to mental energy force.)

Conscious thoughts are wishes, desires, or thoughts that we are aware of or can recall at any given moment.

Unconscious forces represent wishes, desires, or thoughts that, because of their disturbing or threatening content, we automatically repress and cannot voluntarily access.

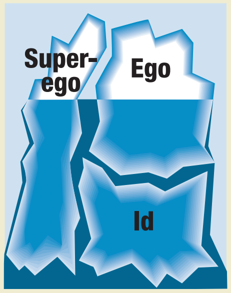
Freud believed that a large part of our behavior was guided or motivated by unconscious forces.

Unconscious motivation is a Freudian concept that refers to the influence of repressed thoughts, desires, or impulses on our conscious thoughts and behaviors.

Freud developed three methods to uncover unconscious processes: ***free association, dream interpretation,*** and ***slips of the tongue*** (Freudian slips).

Divisions of the Mind

Freud divided the mind into three divisions: id, ego, and superego.

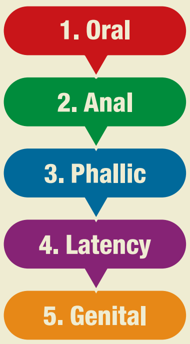


The first division is the ***id,*** which contains two biological drives—sex and aggression—that are the source of all mental energy. The id follows the pleasure principle, which is to satisfy the biological drives.

The second division is the ***ego,*** whose goal is to find socially acceptable ways of satisfying the id's desires within the range of the superego's prohibitions. The ego follows the reality principle, which is to satisfy a wish or desire only if there is a socially acceptable outlet available.

The third division is the ***superego,*** whose goal is to apply the moral values and standards of one's parents or caregivers and society in satisfying one's wishes.

Psychosexual Stages



Freud assumed that our personality develops as we pass through a series of ***five psychosexual stages.***

During these developmental periods—the ***oral, anal, phallic, latency,*** and ***genital stages***—the individual seeks pleasure from different areas of the body associated with sexual feelings. Freud emphasized that the child's first five years were the most important in personality development.

Humanistic Theories

Humanistic theories emphasize our capacity for personal growth, development of our potential, and freedom to choose our destiny. ***Humanistic theories*** stress three major points—phenomenological perspective, holistic view, and self-actualization.

The ***phenomenological perspective*** means that our perception of the world, whether or not it is accurate, becomes our reality.

The ***holistic view*** means that a person's personality is more than the sum of its individual parts; instead, the individual parts form a unique and total entity that functions as a unit.

Self-actualization refers to our inherent tendency to reach our true potentials.

Humanistic theories reject the biological determinism and the irrational, unconscious forces of Freud's psychodynamic theory. Humanistic theories emphasize freely choosing to go after one's dream and change one's destiny.

The beginning of humanistic theory can be traced to two psychologists: Abraham Maslow, who rejected behaviorism's system of rewards and punishment, and Carl Rogers, who rejected Freud's psychodynamic theory with its emphasis on unconscious forces.

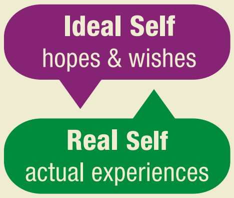
Abraham Maslow

Maslow (1968) broke away from the reward/punishment/observable behavior mentality of behaviorism and developed his humanistic theory. ***Maslow's humanistic theory*** emphasized two things: our capacity for growth or self-actualization and our desire to satisfy a variety of needs.

Maslow's hierarchy of needs arranges needs in ascending order, with biological needs at the bottom and social and personal needs toward the top; as needs at one level are met, we advance to the next level.

Carl Rogers's Self Theory

Carl Rogers rejected the psychodynamic approach because it placed too much emphasis on unconscious, irrational forces. Instead, Rogers developed a new humanistic theory, which is called self theory. ***Rogers's self theory,*** also called self-actualization theory, has two primary assumptions: Personality development is guided by each person's unique self-actualization tendency, and each of us has a personal need for positive regard.



Rogers said that the ***self*** is made up of many self-perceptions, abilities, personality characteristics, and behaviors that are organized and consistent with one another.

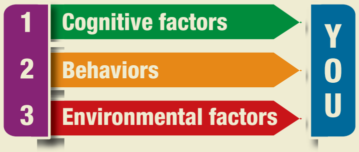
Social Cognitive Theory

Freud's ***psychodynamic theory,*** developed in the early 1900s, grew out of his work with patients. Humanistic theories were developed in the 1960s by an ex-Freudian (Carl Rogers) and an ex-behaviorist (Abraham Maslow), who believed that previous theories had neglected the positive side of human potential, growth, and self-fulfillment.

In comparison, ***social cognitive theory,*** which was developed in the 1960s and 1970s, grew out of a strong research background, unlike the way humanistic and Freudian psychodynamic theories were developed. Social cognitive theory emphasizes a more rigorous experimental approach to develop and test concepts that can be used to understand and explain personality development.



Social cognitive theory says that personality development is primarily shaped by three factors: environmental conditions (learning), cognitive-personal factors, and behavior. ***Behavior*** includes a variety of actions, such as what we do and say. ***Environmental influences*** include our social, political, and cultural influences as well as our particular learning experiences. Just as our cognitive factors influence how we perceive and interpret our environment, our environment in turn affects our beliefs, values, and social roles. ***Cognitive-personal factors*** include our beliefs, expectations, values, intentions, and social roles as well as our biological and genetic influences. Thus, what we think, believe, and feel affects how we act and behave.

Bandura's Social Cognitive Theory

Perhaps the best example of the social cognitive approach is Bandura's social cognitive theory, which he developed in the 1970s. ***Bandura's social cognitive theory*** says that personality development, growth, and change are influenced by four distinctively human cognitive processes: highly developed language ability, observational learning, purposeful behavior, and self-analysis.

Should I take one marshmallow now or wait and get two later?

Bandura's theory emphasizes ***cognitive factors,*** such as personal values, goals, and beliefs. Three particular beliefs have been shown to influence personality development: ***locus of control,*** which refers to how much control we think we have over our environment; ***delay of gratification,*** which involves our voluntarily postponing an immediate reward for the promise of a future reward; and ***self-efficacy,*** which refers to our personal beliefs of how capable we are in performing specific tasks and behaviors.

One of the ***basic assumptions*** of social cognitive theory is that our beliefs, values, and goals influence the development of our personalities, which, in turn, affects how we behave.

Trait Theory

For over 50 years, a ***major goal*** of personality researchers was to find a way to define the structure of personality with the fewest possible traits. The search for a list of traits that could describe personality differences among everyone, including criminals and nuns, began in the 1930s with a list of about 4,500 traits and ended in the 1990s with a list of only 5 traits.

In the 1990s, trait theory developed the five-factor model, which is based on laboratory research, especially questionnaires and statistical procedures. ***Trait theory*** refers to an approach for analyzing the structure of personality by measuring, identifying, and classifying similarities and differences in personality characteristics or traits. The basic unit for measuring personality characteristics is the trait. ***Traits*** are relatively stable and enduring tendencies to behave in particular ways, but behavior is not always the same across different situations.

Trait theory says relatively little about the development or growth of personality but instead emphasizes measuring and identifying differences among personalities.

Five-Factor Model

O
C
E
A
N

The ***five-factor model*** organizes all personality traits into five categories—openness, conscientiousness, extraversion, agreeableness, and neuroticism (OCEAN). These traits, which are referred to as the ***Big Five traits,*** raise three major issues.

First, although traits are stable tendencies to behave in certain ways, this stability does not necessarily apply across situations. According to the ***person-situation interaction,*** you may behave differently in different situations because of the effects of a particular situation.

Second, personality traits are both ***changeable and stable:*** Most change occurs before age 30 because adolescents and young adults are more willing to adopt new values and attitudes or revise old ones; most stability occurs after age 30, but adults do continue to grow in their ideas, beliefs, and attitudes.

Third, ***genetic factors*** have a considerable influence on personality traits and behaviors. Genetic factors push and pull the development of certain traits, whose development may be helped or hindered by environmental factors.

Traits are useful in that they provide shorthand descriptions of people and predict certain behaviors.

H. Application: Assessment—Objective Tests

Definition

Why are traits big business?

The study of traits has become big business because traits are used in constructing personality tests. For example, if you're applying for a job, you may be asked to fill out a written questionnaire, which is really a honesty or integrity test. To help employers make hiring decisions, about 6,000 companies administer integrity tests to weed out dishonest job applicants each year (L. T. Cullen, 2006). These tests aim to predict how likely an applicant is to engage in counterproductive work behaviors (e.g., stealing, arguing, lying, blaming) (C. M. Berry et al., 2007; Spector et al., 2006). Integrity tests, which are the most frequently administered psychological tests in the United States, are examples of objective personality tests (Mumford et al., 2001).

Objective personality tests, also called ***self-report questionnaires,*** consist of specific written statements that require individuals to indicate, for example, by checking "true" or "false," whether the statements apply to them.

I would never give free drinks to my friends—it's against the rules.

Because objective personality tests or self-report questionnaires use very specific questions and require very specific answers, they are considered to be highly ***structured,*** or ***objective.*** In comparison, projective tests (pp. 450–451) use ambiguous stimuli (inkblots or photos), have widely varying responses, and are considered to be ***unstructured,*** or ***projective,*** personality tests.

It is most likely that, as part of a job interview, you will be asked to take a variety of self-report questionnaires. That's because employers, clinicians, researchers, and government and law enforcement agencies use self-report questionnaires to identify and differentiate personality traits.

The basic assumption behind self-report questionnaires brings us back to the definition of traits. We defined traits as stable and enduring tendencies to behave in certain ways. Self-report questionnaires identify traits, which employers use to predict how prospective employees will behave in particular jobs or situations (D. J. Ozer, 1999).

Before we discuss how valid and reliable self-report questionnaires are in predicting behavior, we'll examine two of the more popular self-report questionnaires.

Examples of Objective Tests

How honest are most employees?

Objective personality tests are used in both business and clinical settings. In business settings, self-report questionnaires are often used in selecting employees for certain traits, such as being honest and trustworthy (C. M. Berry et al., 2007; Spector et al., 2006).

Integrity Tests

Would you buy a gold watch from this man?

Integrity or honesty tests are supposed to assess whether individuals have high levels of the trait of honesty. Questions asked on honesty tests are similar to the following (Lilienfeld, 1993):

1. Have you ever stolen merchandise from your place of work?
2. Have you ever been tempted to steal a piece of jewelry from a store?
3. Do you think most people steal money from their workplace every now and then?
4. A person has been a loyal and honest employee at a firm for 20 years. One day, after realizing she neglected to bring lunch money, she takes $10 from her workplace but returns it the next day. Should she be fired?

People strong in the trait of honesty answer: (1) no, (2) no, (3) no, (4) yes.

Notice that some self-report questionnaires, such as the integrity test, focus on measuring a single personality trait—in this case honesty. The next self-report questionnaire, called the MMPI-2, is used primarily in clinical settings and measures a number of traits and personality problems.

Minnesota Multiphasic Personality Inventory-2

Suppose a parole board needed to decide if a convicted murderer had changed enough in prison to be let out on parole. To help make this decision, they might use a test that identifies the range of normal and abnormal personality traits, such as the well-known Minnesota Multiphasic Personality Inventory-2 (MMPI-2), which has recently been updated to include fewer test items while retaining the effectiveness of the longer version (Ben-Porath, 2010). The revised test is named MMPI-2-RF (Restructured Form), but for simplicity, we will continue to refer to it as MMPI-2.

The ***Minnesota Multiphasic Personality Inventory-2-RF (MMPI-2)*** is a true-false self-report questionnaire that consists of 338 statements describing a wide range of normal and abnormal behaviors. The purpose of the MMPI-2 is to measure the personality style and emotional adjustment in individuals with mental illness.

Could a test show if a person were ready for parole?

The MMPI-2 asks about and identifies a variety of specific personality traits, including depression, hostility, high energy, and shyness, and plots whether these traits are in the normal or abnormal range. The statements below are similar to actual statements in the MMPI-2:

- I tire quickly.
- I am not worried about sex.
- I believe people are plotting against me.

One advantage of this test is that it has three kinds of scales: ***validity scales,*** which assess whether the client was faking good or bad answers; ***clinical scales,*** which identify psychological disorders, such as depression or schizophrenia; and ***content scales,*** which identify specific areas, such as the anger scale, which includes references to being irritable and to difficulties controlling anger (R. M. Kaplan & Saccuzzo, 2009).

The MMPI-2 is a commonly used objective test to assess a wide range of personality traits, numerous behaviors, health and psychosomatic symptoms, and many well-known psychotic symptoms (Ben-Porath, 2010).

Another method that claims to identify your particular traits involves astrology.

Photo Credits: all, © PhotoDisc, Inc.

Reliability and Validity

How do horoscopes work?

About 78% of women and 70% of men read horoscopes, and many believe that they are so correct that they were written especially for them (D. F. Halpern, 1998). As you read the horoscope on the right, note how many traits apply to you. Because horoscopes contain general traits, people believe horoscopes were written especially for them, a phenomenon called the Barnum principle (Snyder et al., 1977).

The ***Barnum principle*** (named after the famous circus owner P. T. Barnum) refers to the method of listing many general traits so that almost everyone who reads the horoscope thinks that these traits apply specifically to him or her. But, in fact, these traits are so general that they apply to almost everyone.

SCORPIO
Oct. 24th to Nov. 21st

You are bright, sincere, and likable but can be too hard on yourself.

Astrologers claim they can identify your personality traits by knowing the sign under which you were born. However, researchers found that horoscopes do not assess personality traits for a particular individual, which means horoscopes lack one of the two characteristics of a good test—validity (Hartmann, 2006).

Validity

Students claim that the Scorpio horoscope, which I (R. P.) wrote, is accurate for them. The reason I can write "accurate" horoscopes is that I use the ***Barnum principle,*** which means that I state personality traits in a general way so that they apply to everyone.

I read my horoscope every day, and it's always right on the mark.

Validity means that the test measures what it claims or is supposed to measure.

A personality test that has no validity is no better than chance at describing or predicting a particular individual's traits. For example, researchers found that the 12 zodiac signs were no better than chance at identifying traits for a particular individual (Svensen & White, 1994). Because horoscopes cannot identify or predict traits for a particular person, horoscopes lack validity. The reason horoscopes remain popular and seem to be "accurate" is that astrologers essentially use the Barnum principle, which means their horoscopes are "accurate" for almost everyone. For comparison, integrity tests generally have low validity, while the MMPI-2 has good validity, which means it can describe and predict behaviors for particular individuals (R. M. Kaplan & Saccuzzo, 2009). In addition to validity, a good personality test must also have reliability.

Reliability

Even though horoscopes lack validity, they may actually have the second characteristic of a good personality test—reliability.

Reliability refers to consistency: A person's score on a test at one point in time should be similar to the score obtained by the same person on a similar test at a later point in time.

Horoscopes may be reliable if the astrologer remains the same. Integrity tests and the MMPI-2 have good reliability. However, the MMPI-2 is better than integrity tests because the MMPI-2 has both good validity and reliability, while the integrity test has good reliability but low validity (R. M. Kaplan & Saccuzzo, 2009).

Usefulness

Is a monk or a devil more honest?

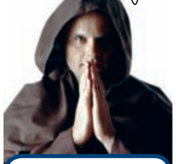
Self-report questionnaires and objective personality tests are popular and widely used because they assess information about traits in a structured way so that such information can be compared with others who have taken the same tests. For example, employers and government and law enforcement agencies use objective personality tests, such as integrity tests, to compare and select certain traits in job applicants (L. T. Cullen, 2006). Researchers use objective personality tests to differentiate between people's traits. Counselors and clinicians use objective personality tests, such as the MMPI-2, to identify personality traits and potential psychological problems (J. R. Graham, 2005). We'll discuss the disadvantages and advantages of objective personality tests.

Disadvantages

One disadvantage of objective personality tests is that their questions and answers are very structured, and critics from the psychodynamic approach point out that such structured tests may not assess deeper or unconscious personality factors. A second disadvantage comes from the straightforward questions, which often allow people to figure out what answers are most socially desirable or acceptable and thus bias the test results. For example, one problem with integrity tests is that the answers can be faked so that the person appears more trustworthy (compare the devil's and monk's responses on the right) (L. T. Cullen, 2006). Third, many self-report questionnaires measure specific traits, which we know may predict behavior in the same situations but not across situations. This means a person may behave honestly with his or her family but not necessarily with his or her employer.

Of course, I'm a very, very honest person.

I'm not as honest as I should be.



Which of these two would you trust?

Advantages

One advantage of objective personality tests is that they are easily administered and can be taken individually or in groups. A second advantage is that, since the questions are structured and require either a true-false or yes-no answer, the scoring is straightforward. Third, many of the self-report questionnaires have good reliability. For example, the reliability of the MMPI-2 ranges from 0.70 to 0.85 (1.0 is perfect reliability) (R. M. Kaplan & Saccuzzo, 2009). Fourth, the validity of self-report questionnaires varies with the test; it ranges from poor to good. For example, the validity of integrity tests appears to be poor: In one study, a group of monks and nuns scored "more dishonest" than a group of prisoners in jail (Rieke & Guastello, 1995). In comparison, many studies on the MMPI-2 indicate that its validity is good (R. M. Kaplan & Saccuzzo, 2009).

Because objective personality tests and projective personality tests (pp. 450–451) have different advantages and disadvantages, counselors and clinical psychologists may use a combination of both to assess a client's personality traits and problems.

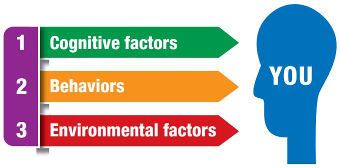
Summary Test

A. Social Cognitive Theory



1. One theory says that personality development is shaped primarily by environmental conditions (learning), cognitive-personal factors, and behavior, which all interact to influence how we evaluate, interpret, and organize information and apply that information to ourselves and others; this is called the ________________ theory.

2. Albert Bandura called the version of his original social learning theory the (a) ________________ theory. Bandura's theory assumes that four distinctively human cognitive processes—highly developed language ability, observational learning, purposeful behavior, and self-analysis—influence the growth, development, and change in (b) ________________.

3. Our highly developed (a) ________________ ability provides us with a tool for processing and understanding information, which is critical to personality development. Our capacity for (b) ________________ learning allows us to learn through watching, without observable behavior or a reinforcer. Our capacity for forethought enables us to plan ahead and set goals—to perform (c) ________________ behavior. Finally, the fact that we can monitor our thoughts and actions as well as set and change goals and values gives us the capacity for (d) ________________.

4. The power of beliefs and ideas to change the way that we interpret situations and events is one of the basic assumptions of social cognitive theories. Rotter developed a scale to measure our belief about how much control we have over situations or rewards; he called this belief (a) ________________. If we believe that we have control over situations and rewards, we are said to have an (b) ________________ locus of control. In contrast, if we believe that we do not have control over situations and rewards and that events outside ourselves determine what happens, we are said to have an (c) ________________ locus of control.

5. According to Bandura, our personal belief regarding how capable we are of exercising control over events in our lives is called (a) ________________. According to Mischel, our voluntary postponement of an immediate reward and persistence in completing a task for the promise of a future reward is called delay of (b) ________________.

B. Trait Theory

6. A relatively stable and enduring tendency to behave in a particular way is called a (a) ________________. An approach to understanding the structure of personality by measuring, identifying, and analyzing differences in personality is called (b) ________________ theory. In attempting to pare down a list of traits by finding relationships among them, researchers have used a statistical method called (c) ________________.

7. The model that organizes all personality traits into five categories is called the (a) ________________. These five categories, known as the Big Five, are (b) ________________, ________________, ________________, ________________, and ________________; their initial letters spell the word OCEAN.

8. Mischel questioned the basic assumption of trait theory, saying that, if traits represent consistent behavioral tendencies, they should predict behaviors across many different (a) ________________. Instead, he found that people behaved with great consistency in the same situation but behaved with low consistency across different situations. Mischel pointed out that predicting a person's behavior must take into account not only the person's traits but also the effects of the situation; this idea became known as the (b) ________________ interaction.

C. Genetic Influences on Traits

9. How inherited or genetic factors influence and interact with psychological factors—for example, the ways we behave, adapt, and adjust to our environments—is the focus of the field of behavioral (a) ________________. Current thinking about genetic factors is that they do not fix behaviors but rather set a range for behaviors. Researchers estimate genetic influences with a measure that estimates how much of some behavior is due to genetic influences; this measure is referred to as (b) ________________.

10. Considering the various influences on personality development, researchers estimated that about 40% of the influence comes from (a) ________________, which are inherited. About 27% of the influence on personality development comes from environmental factors that involve how each individual reacts and adjusts to his or her own environment; these are called (b) ________________ factors. About 7% of the influence on personality development comes from environmental factors that involve parental patterns and shared family experiences; these are called (c) ________________ factors. The remaining 26% of the influence on personality development cannot as yet be identified and is attributed to errors in testing and measurement procedures.

D. Evaluation of Trait Theory

11. Trait theory assumes that differences among personalities can be described by a short but comprehensive list of traits. Critics of the current list, known as the (a) ______________, point out that the data for the model may paint too simplistic a picture of human personality and may not reflect its depth and complexity. Trait theory assumes that traits are consistent and stable influences on our (b) ______________, but critics argue that when traits are measured in one situation, they do not necessarily predict behaviors in other situations.

12. The biggest changes in personality occur during childhood, adolescence, and young adulthood because young men and women are somewhat more likely to be open to new ideas. Personality is less likely to change after age (a) ______________. Observations from twin studies indicate that (b) ______________ factors significantly influence personality traits. Critics warn that inherited factors should not be exaggerated because 50% or more of the influence on traits comes from (c) ______________ influences.

E. Research Focus: 180-Degree Change

13. If you were to experience a sudden and radical or dramatic shift in personality, beliefs, or values, you would be said to have experienced a (a) ______________ in personality. One way researchers studied these changes in personality was to ask each individual the same set of relatively narrow and focused questions so that the same information was obtained from everyone; this method is called the (b) ______________.

F. Cultural Diversity: Suicide Bombers

14. Individuals who volunteer to become suicide bombers do so for both strong (a) ______________ and ______________ reasons. Personal reasons may include such things as wanting to avenge the death of a loved one. Almost all suicide bombers are raised in the Muslim culture, whose beliefs hold that individuals who die as suicide bombers are considered (b) ______________, who are revered in this culture as prophets.

15. In pursuing their goals, violent Muslim groups will continue to use suicide bombers because they have widespread (a) ______________ approval and are an effective method of killing, instilling (b) ______________, and spreading their political (c) ______________.

G. Four Theories of Personality

Super-ego
Ego
Id
Ideal Self
Real Self
OCEAN

16. How does personality grow and develop? We discussed four different answers. The theory that emphasizes the importance of early childhood, unconscious factors, the three divisions of the mind, and psychosexual stages is called (a) ______________. The theories that focus on the phenomenological perspective, a holistic view, and self-actualization are called (b) ______________ theories. The theory that says that personality development is shaped by the interaction among three factors—environmental conditions, cognitive-personal factors, and behavior—is called (c) ______________ theory. The theory that emphasizes measuring and identifying differences among personalities is called (d) ______________ theory.

H. Application: Assessment—Objective Tests

17. Self-report questionnaires, which consist of specific written statements that require structured responses—for example, checking "true" or "false"—are examples of ______________ personality tests.

18. A true-false self-report questionnaire containing hundreds of statements that describe a wide range of normal and abnormal behaviors is called the (a) ______________. The purpose of this test is to distinguish normal from (b) ______________ groups.

19. The method of listing a number of traits in such a general way that almost everyone who reads a horoscope thinks that many of the traits apply specifically to him or her is called the ______________ principle.

Answers: *1. social cognitive; 2. (a) social cognitive, (b) personality; 3. (a) language, (b) observational, (c) purposeful, (d) self-analysis; 4. (a) locus of control, (b) internal, (c) external; 5. (a) self-efficacy, (b) gratification; 6. (a) trait, (b) trait, (c) factor analysis; 7. (a) five-factor model, Big Five, (b) openness, conscientiousness, extraversion, agreeableness, neuroticism; 8. (a) situations, (b) person-situation; 9. (a) genetics, (b) heritability; 10. (a) genetic factors, (b) nonshared environmental, (c) shared environmental; 11. (a) Big Five, (b) behaviors; 12. (a) 30, (b) genetic, (c) environmental; 13. (a) quantum change, (b) structured interview; 14. (a) personal, cultural, (b) martyrs; 15. (a) cultural, (b) fear, (c) message; 16. (a) Freud's psychodynamic theory, (b) humanistic, (c) social learning, (d) trait; 17. objective; 18. (a) Minnesota Multiphasic Personality Inventory-2, or MMPI-2, (b) abnormal; 19. Barnum*

Critical Thinking

Personality Tests Help Employers Find Applicants Who Fit

More and more job applicants are being required to take personality tests. Already, at least one-third of employers, ranging from governments to hospitals, retail stores to restaurants, and airlines to manufacturing plants, use personality tests in their hiring and promotion process.

There are many personality tests, and each measures something different. For instance, the Myers-Briggs measures personality traits necessary for leadership and teamwork and is used by 89 of the Fortune 100 companies. The Minnesota Multiphasic Personality Inventory (p. 474) measures an individual's tendency toward substance abuse and psychopathology and is used by 60% of police departments as a way to screen applicants. Personality tests look at a variety of other characteristics such as thought processes, sociability, motivation, self-awareness, emotional intelligence, stress management, dependability, and work style.

Some experts believe personality tests are overused and overinterpreted, and caution employers about the potential negative impact the use of the tests may have on minority applicants. Others believe personality tests have an important place in the hiring process because the tests can predict how well an applicant "fits" with the job description. For instance, when hiring a salesperson, a company can have a list of the personality traits of successful salespeople and then match an applicant's test results against that standard.

Many companies that have used personality tests showed a decrease in absenteeism and turnover, which means big savings for the company. By using personality tests, one California theme park increased levels of employee retention and customer satisfaction, and reduced levels of absenteeism and theft. Also, a bottling company in Milwaukee reduced the number of sick days in half and an airline reduced tardiness by one-third.

Personality tests are increasingly being used in the hiring process to supplement interviews and a resumé review. So, how should you respond to test questions to be sure you get the job? Although ideal responses vary by job position and company, experts suggest that you not falsify your responses, as many personality tests have a sophisticated way of knowing if you're lying. Luis Valdes, an executive consultant, explains, "For any given character trait, say independence, there's an optimal amount. If a person seems to be really extreme, well, most people aren't that extreme, so it suggests they tried to answer all the questions in a positive but not very realistic way" (Valdes, 2006). In the case of personality tests, it appears that honesty is the best policy. (Adapted from Cha, 2005; L. T. Cullen, 2006; Frieswick, 2004; Gladwell, 2004; Gunn, 2006; C. Smith, 1997; Valdes, 2006; Wessel, 2003)

QUESTIONS

1 Why do some employers use both interviews and objective personality tests in deciding whom to hire?

2 Why do companies look for certain traits in selecting employees, and why would Freud question the importance of selecting for traits?

3 If you were using the Big Five traits to design a test for salespeople who work as a team, which traits would you look for?

4 What are some objections to or disadvantages of using objective personality tests in the hiring process?

5 An applicant's behavior during an interview is important, but does it generalize to good behavior on the job? Why or why not?

6 Which objective personality test has a scale to detect lying? Can objective personality tests prevent a person from "faking his or her character"?

Suggested Answers to Critical Thinking

1. Some employers believe that applicants may not always be truthful in interviews and that objective personality tests may be more difficult to fool.
2. Employers are looking for certain traits because, according to trait theory, traits are relatively stable and enduring tendencies to behave in certain ways and traits predict how people will behave in similar situations. Freud would point out that traits are important but that behaviors and feelings may be influenced by unconscious forces, of which applicants would not be aware and which are not easily measured by objective personality tests.
3. Salespeople who work as a team might be selected for being high in openness (open to new experiences), extraversion (outgoing and decisive), agreeableness (warm and good-natured), and conscientiousness (responsible and dependable) but low in neuroticism (stable and not a worrier).
4. Since objective personality tests use very structured questions, simplified yes-no answers, and objective scoring, an applicant can sometimes figure out and give socially acceptable answers and thus bias the test in his or her favor. Also, some applicants, especially those already in upper-management positions, find the use of personality tests during the hiring process to be offputting.
5. A person's behavior during a job interview doesn't necessarily predict good behavior on the job. The reason is the person-situation interaction, which states that people may behave differently because different situations create different cues to which they will respond.
6. The MMPI-2 has a scale to detect lying. To some degree, people may "fake their character" on objective personality tests provided they can figure out the socially acceptable or desirable answers while still being able to pass the test's lie detector.

Stress

Why does Luisa fear she will die?

One afternoon, Luisa, a 23-year-old college student, was walking on campus and she suddenly felt her heart rate rapidly accelerate, her throat tighten up, and her arms and legs tremble. She became so nauseous she almost vomited. Luisa felt she had no control over what was happening, and when she went to the doctor, she was told nothing was wrong. Still, she worried she might experience something like this again. Then, weeks later, while at the movies, she had another episode during which she experienced dizziness, chest pain, shortness of breath, and weakness in her legs and feet. She feared she was having a heart attack and might die, but after a series of tests, her doctors found no medical problem. About a month later, Luisa had her most serious attack while sitting in her physics class. This time she had a strong desire to leave the classroom, and as soon as she got outside, her legs gave in and she fell to the floor. From then on, Luisa became fearful of places that were closed in or crowded, such as shopping malls, restaurants, theaters, and even classrooms. She avoided these places in fear she would have another crisis. After this most recent episode, she was diagnosed with panic disorder (adapted from Di Salvo, 2006).

23-year-old Luisa has severe anxiety.

Panic disorder is characterized by recurrent and unexpected panic attacks (described below). The person becomes so worried about having another panic attack that this intense worrying interferes with normal psychological functioning (APA, 2000).

The symptoms Luisa had while walking on campus, watching a movie, and sitting in class indicate she was having a ***panic attack,*** a period of intense fear or discomfort in which four or more of the following symptoms are present: pounding heart, sweating, trembling, shortness of breath, feelings of choking, chest pain, nausea, dizziness, and fear of losing control or dying (APA, 2000).

In any given year, about one-third of American adults have at least one panic attack, but most of these adults never develop repeated panic attacks. Like Luisa, about 4% of adults in the United States suffer from panic disorder (Halbreich, 2003). Also, as in Luisa's case, the onset of panic disorder typically occurs during late adolescence or early adulthood (Pine, 2000). Compared with most people who may experience only mild forms of anxiety, people who have panic attacks find their experiences to be very stressful.

Stress is the anxious or threatening feeling that comes when we interpret or appraise a situation as being more than our psychological resources can adequately handle (Lazarus, 1999).

The study of stress is very much the study of how the mind and body interact. In this module, you'll learn how your mind is involved in what happens to your body during stressful situations.

Just as we can use our mind to overreact to stress, we can also use it to cope with stress, which is something Brenda must do almost every minute of her life.

Coping

How has Brenda's life changed?

As you approach Brenda Combs's third- and fourth-grade classroom, you hear her enthusiastically lead her students in joyful singing. Brenda has become an extraordinary educator of at-risk children, making a tremendous impact on the lives of her students. But, the hours are long, the stress is high, and the pay is so low she has to also work part-time jobs to make ends meet. She does this all while being a responsible and loving single mother to her son, Mycole, who suffered a massive stroke at birth and requires special care, and being a graduate school student (she earned her master's degree and is now working toward her Ed.D.).

Brenda's story is especially impressive because about ten years ago, she was a homeless crack addict and a petty criminal, who had been shot, beaten, and raped during her years living on the streets. She was fortunate to have escaped many life-threatening moments. Most people would have expected Brenda's life to continue to spiral downward, but Brenda received a wake-up call serious enough to motivate her to drastically improve her life.

The turning point for Brenda was the morning she woke up to find that her shoes had been stolen from her feet as she slept in an alleyway. The day was so scorching hot she couldn't walk anywhere barefoot. But, more than shoes were stolen from Brenda that morning—her last shred of dignity was taken too. At this point, Brenda took complete charge of her life. She is now clean of drugs, lives in a home with her son, and is an inspirational role model to people everywhere (adapted from APB, 2009; Celizic, 2007; K. Miller, 2007).

How does Brenda cope with being a single mother, student, teacher, and recovering crack addict?

For Brenda, her adult life has presented a series of non-stop potential stressors. To keep these stressors from growing out of control, she uses a variety of coping techniques. Spirituality and taking one day at a time are a couple ways she copes. As you can imagine, she must continually guard against being overwhelmed by school, by work, by being a single mother, and by all the other responsibilities of life. One of the interesting topics we'll discuss in this module is the different ways to cope with stressors.

What's Coming

We'll discuss how you decide something is stressful, your physiological and psychological responses to stress, how your immune system works, how you develop psychosomatic symptoms, which situational, personality, and social factors help or hinder your coping processes, and how to develop a stress management program.

We'll begin with how Luisa's mind can make her physical symptoms worse for no good reason.

Photo Credit: right, Courtesy of Brenda Combs

A. Appraisal

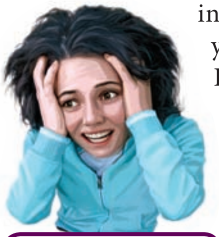
Primary Appraisals

What makes Luisa's symptoms so stressful?

Although Luisa believes she will die during a panic attack, in fact that is impossible ("Panic attacks," 2005). If there is no real threat to Luisa's survival, then why does she react so strongly to her physical symptoms (dizziness, trembling)? One explanation is she may misinterpret normal physical symptoms as serious problems, which can intensify the symptoms. For example, Luisa may be nervous about school grades or going on a date and experience that nervousness physiologically (sweating, racing heart). These symptoms can make her feel more anxious ("What is wrong with me?"), escalating the physical sensations into the chest pain of a heart attack (Ham, 2005). In this example, Luisa's initial interpretation of her physical symptoms is that a stressful situation is happening ("Something is wrong with me and I could die"). The initial interpretation of a potentially stressful situation is called a primary appraisal (Lazarus, 1999, 2000).

***Primary appraisal* refers to our initial, subjective evaluation of a situation, in which we balance the demands of a potentially stressful situation against our ability to meet these demands.**

For example, there can be three different primary appraisals when experiencing a racing heart rate. If a doctor gives you medication to treat a painful headache and says you will initially feel your heart racing, your primary appraisal of your racing heart is that it is irrelevant (your real concern is your headache) and therefore mostly nonstressful. If you're running a marathon and feel your heart beating quickly, your primary appraisal is positive and mostly nonstressful because it makes you feel good. If you're trying to sleep or relax and your heart rate accelerates, your primary appraisal of this situation is stressful. Your primary appraisal that a situation is stressful involves three different interpretations: harm/loss, threat, or challenge.



Luisa's mind creates her intense fear.

Harm/Loss

If you broke your arm in a bike accident, you would know that you have suffered harm or loss.

A *harm/loss appraisal* of a situation means that you have already sustained some damage or injury.

Because the harm/loss appraisal ***elicits negative emotions,*** such as fear, depression, fright, and anxiety, you will feel stressed; and the more intense your negative emotions are, the more stressful and overwhelming the situation will seem.

Harm/loss appraisal

Threat

If you have a terrible fear of giving blood and are asked to do so, you would automatically interpret giving blood as a threat to your well-being.

A *threat appraisal* of a situation means that the harm/loss has not yet taken place but you know it will happen in the near future.

Because a threat appraisal also ***elicits negative emotions,*** such as fear, anxiety, and anger, the situation or event may seem especially stressful. In fact, just imagining or anticipating a threatening situation, such as giving blood or taking a final exam, can be as stressful as the actual event itself.

Threat appraisal

Environmental Factors

If you are working hard in college but find that you have to take two more classes, you might interpret taking these classes as a way to achieve a major goal—that is, you use a challenge appraisal.

A *challenge appraisal* means you have the potential for gain or personal growth but you also need to mobilize your physical energy and psychological resources to meet the challenging situation.

Because a challenge appraisal ***elicits positive emotions,*** such as eagerness or excitement, it is usually less stressful than a harm/loss or a threat appraisal.

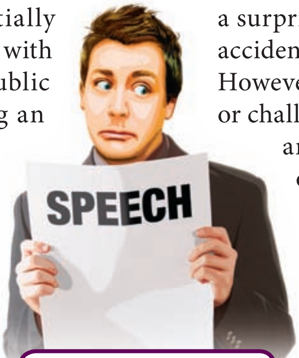
Challenge appraisal

Situations and Primary Appraisals

First reaction. Your first reaction to a potentially stressful situation, such as waiting in line, dealing with a sloppy roommate, giving blood, making a public speech, dealing with a rude salesperson, taking an exam, seeing a vicious dog, or being in a car accident, is to appraise the situation in terms of whether it harms, threatens, or challenges your physical or psychological well-being.

Making primary appraisals about complex situations, such as whether to take a certain job, get married, or go on to graduate school, may require considerable time as you think over the different ways a situation will affect you. In comparison, making primary appraisals about very emotional situations, such as taking a surprise quiz, presenting a report in class, or getting into a car accident, may occur quickly, even automatically (Lazarus, 2000). However, not all appraisals neatly divide into harm/loss, threat, or challenge. Some primary appraisals are a combination of threat and challenge. For instance, if you are about to ask someone for a first date, you may feel threatened by the possibility of being rejected yet challenged by the chance to prove yourself.

Later in this module, we'll discuss how you can change a threat appraisal into more of a challenge appraisal and thus reduce your stressful feelings (N. Skinner & Brewer, 2002). At this point, just keep in mind that making a primary appraisal is the first step in experiencing stress. Depending on the kind of primary appraisal, your level of stress may either increase or decrease.



This person made a primary appraisal that giving a speech was a threat to his self-esteem.

Photo Credits: all center, © PhotoDisc, Inc.

Appraisal and Stress Level

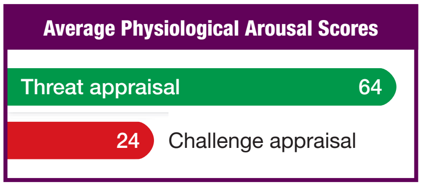
Would it stress you to watch a bloody accident?

If you were asked to watch a film of bloody accidents caused by power saws, how much would your primary appraisal affect your level of stress? This is exactly what researchers asked subjects to do while they recorded a major sign of physiological arousal, called the galvanic skin response.

The ***galvanic skin response*** is a measure of how much a person's hand sweats due to physiological arousal and not to normal temperature changes.

As subjects watched the accident film, they were given instructions that would result in making a primary appraisal of challenge or threat. To encourage challenge appraisals, subjects were told to watch the film objectively, to consider how these accidents might be prevented, but not to identify with the injured. To encourage threat appraisals, subjects were told to put themselves in the place of men who accidentally cut off their fingers and imagine how they would feel.

Level of stress from watching a bloody accident depended on threat or challenge appraisal.



As the graph below shows, subjects using threat appraisals showed significantly more physiological arousal—that is, higher levels of galvanic skin responses—than subjects using challenge appraisals (Dandoy & Goldstein, 1990). Researchers concluded that in threatening or disturbing situations, your feelings of stress increase with the kind of appraisal: Threat appraisals raise levels of stress more than challenge appraisals do. However, when people are asked to identify the cause of their stressful feelings, they usually—and often incorrectly—point to a particular situation rather than to their primary appraisals. As you'll see next, people often appraise the same situation in different ways.

Same Situation, Different Appraisals

How stressful is waiting in line?

When we ask our students, "What stresses you?" they always list a variety of situations, including many of those situations listed in the table below right. Notice especially how the same situation was stressful for some but not for others. For example, 65% said waiting for a late person was stressful, but 35% reported it wasn't. Similarly, 61% said waiting in line was stressful, but 39% said it wasn't. Because people don't agree on which situations are stressful, researchers concluded that level of stress depends not only on the kind of situation but also on the kind of ***primary appraisal*** one makes (G. Fink, 2007; C. Rasmussen et al., 2000). For example, you could appraise waiting in line to get your favorite beverage as a challenge, which elicits positive emotions and little stress. In contrast, you could appraise waiting in line as a threat or real test of your patience, which elicits negative emotions (growing impatient) and considerable stress. Thus, similar situations (waiting in line) can result in different levels of stress depending on your primary appraisals.

	Percentage rating it	
Situation	**stressful**	**not stressful**
Waiting for someone who is late	65	35
Being caught in traffic	63	37
Waiting in line	61	39
Waiting in a doctor's office	59	41
Waiting for the government to act	51	49
Waiting for a repair person	46	54
Looking for a parking space	42	58
Waiting for an airplane to take off	26	74

Why are 61% stressed by waiting in line while 39% are not?

Sequence: Appraisal to Arousal

How does stress start?

The first step in feeling stress depends on your primary appraisal, which can be one of harm/loss, threat, or challenge. In turn, harm/loss and threat appraisals elicit negative emotions, which, in turn, increase levels of stress. In comparison, challenge appraisals elicit positive emotions, which, in turn, decrease levels of stress. Thus, when you say that a situation is causing you stress, such as giving blood, taking an exam, making a public speech, changing your job, asking for a date, arguing with your boss, having to move, getting married, or arguing with your roommate, you are forgetting that part of the stress is coming from whether you make a harm/loss or threat appraisal versus a challenge appraisal (Lazarus, 2000).

The moment after you make an appraisal, especially a harm/loss or threat appraisal, your body changes from a generally calm state into a state of heightened physiological arousal as it prepares to deal with the stressor, whether it involves a car accident, a mugger, a speech, or giving blood. We'll look inside the body and see what happens when you are stressed.

Making a threat or harm/loss appraisal results in increased physiological arousal.

Figure/Text Credit: Situation list data from *USA Today*, August 19, 1987, p. 4D.

B. Physiological Responses

Fight-Flight Response

What happens when you're frightened?

Imagine giving a talk in class. As you look at everyone staring at you, you feel your heart pounding, mouth becoming dry, hands sweating, stomach knotting, and muscles tensing; you take in short, rapid breaths. Your body is fully aroused before you have spoken a single word (Tanouye, 1997). About 40% of adults report fear of speaking in public (A. Lewis, 2001).

Since speaking in public is no threat to your physical survival and you can neither fight nor flee, why is your body in this state of heightened physiological arousal? The answer is that once you make a primary appraisal that something is a threat—whether it's giving a speech or facing a mugger—these threatening and fearful thoughts automatically trigger one of the body's oldest physiological response systems, the fight-flight response (J. M. White & Porth, 2000).

The fight-flight response helps us survive by preparing the body for action—fleeing or fighting.

The ***fight-flight response*** (a) directs great resources of energy to the muscles and the brain; (b) can be triggered by either physical stimuli that threaten our survival or psychological situations that are novel, threatening, or challenging; and (c) involves numerous physiological responses that arouse and prepare the body for action—fight or flight.

We know that the fight-flight response is evolutionarily very old because it can be found in animals such as the alligator, which has been around for millions of years. We presume that our early ancestors evolved a similar fight-flight response to help them survive attacks by wild animals and enemies.

Physical stimuli. Today you have almost no need to fight wild animals or flee attacking enemies, so you rarely activate your fight-flight response for the reasons important to our early ancestors. However, you would activate the fight-flight response when faced with a potentially dangerous physical stimulus, such as a mugger, accident, police siren, snake, tornado, or other situation that threatened your physical survival.

Psychological stimuli. Today the most common reason you activate the fight-flight response is exposure to potentially bothersome or stressful psychological stimuli, such as worrying about exams, being impatient in traffic, having to wait in lines, getting angry over a putdown, or arguing with someone (Lazarus, 2000). We'll trace the sequence of how psychological or physical stimuli can trigger the fight-flight response and transform your body into a state of heightened physiological arousal (J. M. White & Porth, 2000).

Sequence for Activation of the Fight-Flight Response

1 Appraisal

A number of potentially dangerous physical stimuli, such as seeing a snake or being in an accident, can automatically trigger the fight-flight response. But much more common triggers of the fight-flight response are hundreds of psychological stimuli that you appraise as threatening, such as making a public speech or taking an exam. Thus, either ***physically or psychologically threatening stimuli*** can trigger the fight-flight response and negative emotional feelings (fear, rage).

2 Hypothalamus

If you appraise making a public speech as psychologically threatening, these thoughts activate a part of your brain called the ***hypothalamus.*** In turn, the hypothalamus simultaneously activates two stress-related responses: It triggers the pituitary gland to release a stress-fighting hormone called ***ACTH*** (adrenocorticotropic hormone), and it activates the sympathetic division of the autonomic nervous system.

Autonomic Nervous System

3 Sympathetic Division

As we discussed earlier (p. 81), the autonomic nervous system has two divisions. The ***sympathetic division,*** which is activated by the hypothalamus, triggers a number of physiological responses that make up the fight-flight response, which prepares the body to deal with potentially threatening physical or psychological stimuli. In contrast, the ***parasympathetic division,*** also activated by the hypothalamus, returns the body to a more calm, relaxed state.

4 Fight-Flight Response

The sympathetic division triggers a very primitive ***fight-flight response*** (present in crocodiles), which causes great ***physiological arousal*** by increasing heart rate, blood pressure, respiration, secretion of excitatory hormones, and many other responses that prepare the body to deal with an impending threat, whether speaking in public or facing a mugger.

Next, we'll describe the many interesting physiological responses that transform the body into a powerful fighting or fleeing machine.

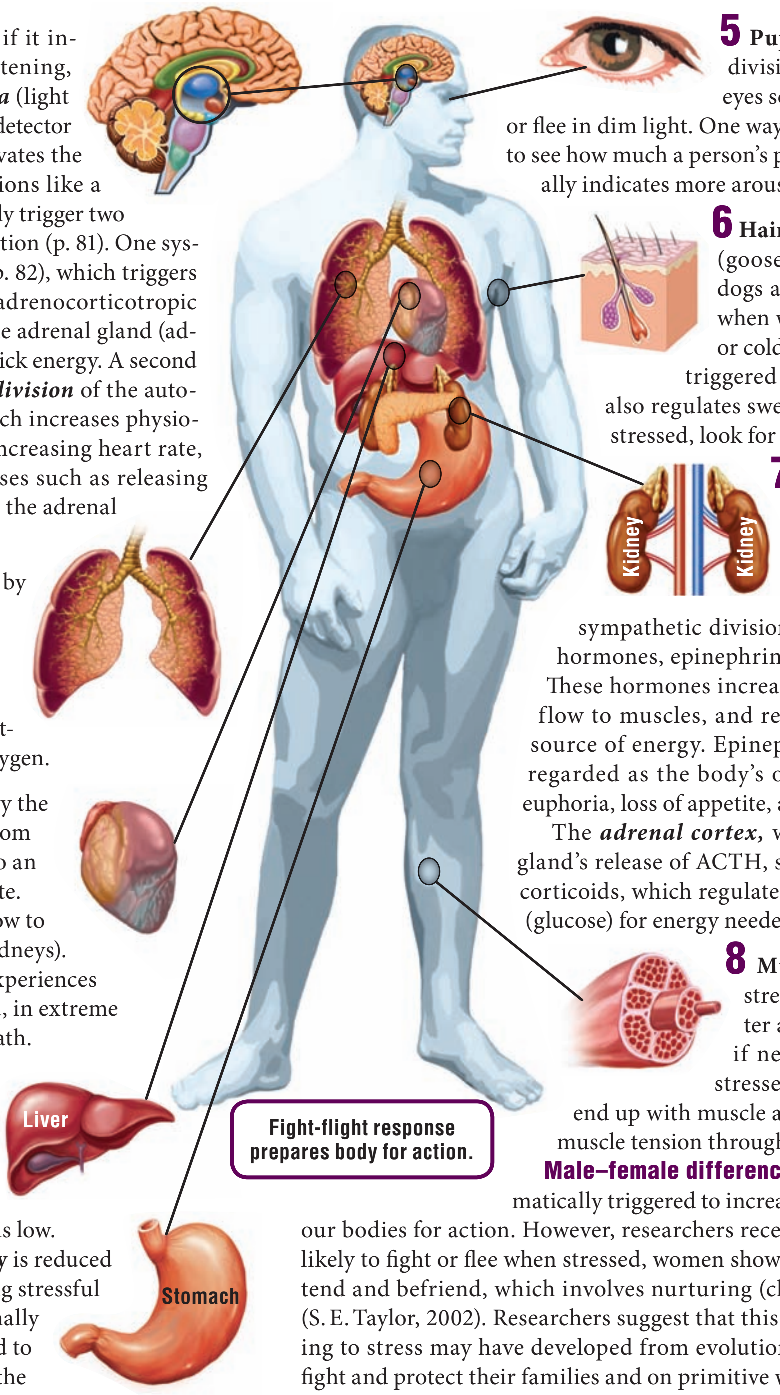
Fight-Flight: Physiological and Hormonal Responses

I hate to speak in public!
SPEECH

Physical or psychological stimuli can trigger the fight-flight response.

It is difficult to believe that the powerful fight-flight response can be triggered just as easily by potentially threatening psychological stimuli, such as speaking in public or taking exams, as by potentially threatening physical stimuli, such as seeing a rattlesnake. Although you rarely experience potentially threatening physical stimuli, such as meeting a snake, you do face many psychological situations that you appraise as threatening—"Let me tell you about my terrible day." As soon as you appraise a situation as threatening, specific parts of your brain start the fight-flight response, which in turn prepares your body for action (Cowley, 2003). We'll describe some of the major physiological changes triggered by the fight-flight response (S. Johnson, 2003).



Fight-flight response prepares body for action.

1 A **stress appraisal,** especially if it involves something fearful or threatening, can instantly activate the ***amygdala*** (light blue), which functions like a threat detector p. 363). In turn, the amygdala activates the ***hypothalamus*** (red), which functions like a switch to quickly and simultaneously trigger two systems that arouse the body for action (p. 81). One system involves the ***pituitary gland*** (p. 82), which triggers a release of the hormone ACTH (adrenocorticotropic hormone), which acts on part of the adrenal gland (adrenal cortex) to increase fuel for quick energy. A second system involves the ***sympathetic division*** of the autonomic nervous system (p. 72), which increases physiological arousal by automatically increasing heart rate, blood pressure, and other responses such as releasing powerful arousing hormones from the adrenal glands (see #7 on the right).

2 **Respiration,** which is increased by the sympathetic division, is more rapid and shallow so that there is a greater flow of oxygen into the body. However, if breathing is too rapid and shallow, we may feel lightheaded or "spacey" from lack of oxygen.

3 **Heart rate,** which is increased by the sympathetic division, can rocket from a normal 70–90 beats per minute to an incredible 200–220 beats per minute. Rapid heart rate increases blood flow to muscles and vital organs (lungs, kidneys). Rapid heart rate during stressful experiences can lead to a "pounding heart" and, in extreme cases, result in heart attack and death.

4 The **liver** releases its stores of blood sugar (glycogen) to provide a ready source of energy during stress. After a stressful experience, we may feel fatigued because our supply of blood sugar is low.

Stomach and **intestinal activity** is reduced by the sympathetic division. During stressful experiences, the blood that is normally used by digestive organs is rerouted to muscles and vital organs. Because the sympathetic division shuts down the digestive system, people may experience problems with digestion, such as stomach pain, constipation, and diarrhea, during stressful times.

5 **Pupils** are dilated by the sympathetic division. As a result, more light enters our eyes so we can see better if we have to fight or flee in dim light. One way to check for physiological arousal is to see how much a person's pupils are dilated: More dilation usually indicates more arousal (except in the case of drug use).

6 **Hair** stands up; this is called piloerection (goose bumps) and is more noticeable in dogs and cats. Piloerection, which occurs when we are stressed (frightened or angry) or cold (fluffy fur or hair conserves heat), is triggered by the sympathetic division, which also regulates sweating. The next time you are feeling stressed, look for piloerection and sweaty hands.

7 **Adrenal glands,** which are located above the kidneys, have an outside—adrenal cortex—and an inside—adrenal medulla. The ***adrenal medulla,*** which is activated by the sympathetic division, secretes two powerful activating hormones, epinephrine (adrenaline) and norepinephrine. These hormones increase heart rate, blood pressure, blood flow to muscles, and release of blood sugar (glucose) as a source of energy. Epinephrine and norepinephrine may be regarded as the body's own stimulants; they can result in euphoria, loss of appetite, and sleeplessness.

The ***adrenal cortex,*** which is activated by the pituitary gland's release of ACTH, secretes a group of hormones called corticoids, which regulate levels of minerals and increase fuel (glucose) for energy needed to take some action.

8 **Muscle tension** is increased during stressful experiences, so that we are better able to coordinate and move quickly if needed. However, if you are feeling stressed for long periods of time, you may end up with muscle aches and pains because of increased muscle tension throughout your body.

Male–female difference. The fight-flight response is automatically triggered to increase physiological arousal and prepare our bodies for action. However, researchers recently found that while men are more likely to fight or flee when stressed, women show a different response to stress, called tend and befriend, which involves nurturing (children) and seeking social support (S. E. Taylor, 2002). Researchers suggest that this male–female difference in responding to stress may have developed from evolutionary pressures on primitive men to fight and protect their families and on primitive women to nurture their children and seek help and social support for themselves and their families.

Although the fight-flight response is designed to aid survival in stressful situations, if the fight-flight response is continuously triggered over a period of time (days, weeks), you may develop painful physical problems, which we'll describe next.

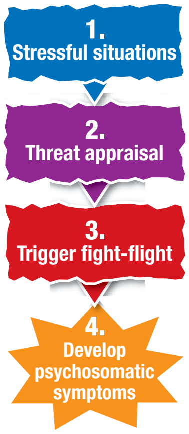
B. Physiological Responses

Psychosomatic Symptoms

What causes stomach pains?

As a college freshman, Joan was stressed out from having too many classes, spending 28 hours a week on homework, working another 10 hours a week at a part-time job, and not getting enough sleep. Joan is one of the 30% of college students in the United States who reported feeling "frequently overwhelmed" by all they have to do (Sax, 2002). Women report more stress (37%) than men (17%), who seem to reduce stress by exercising, partying, and playing more video games than women (Deckro, 2002; Gallagher, 2002). If stress persists for weeks and months, there is a good possibility that you will develop one of a variety of unwanted psychosomatic (also called psychophysiological) symptoms (Kemeny, 2003; Selye, 1993).

Psychosomatic** (SIGH-ko-so-MAH-tick) **symptoms are real and sometimes painful physical symptoms, such as headaches, muscle pains, stomach problems, and increased susceptibility to colds and flu, that are caused by increased physiological arousal that results from psychological factors, such as worry, stress, and anxiety. (The word *psychosomatic* is derived from *psyche* meaning "mind" and *soma* meaning "body.")



"The fact is that we're now living in a world where our bodies aren't allowed a chance to rest... they're being driven by inadequate sleep, lack of exercise, by smoking, by isolation or frenzied competition" (McEwen, 2002). Although our bodies are cleverly designed to use the fight-flight response to deal with relatively infrequent stressors, our bodies do need time for rest and relaxation. However, for many, the busy and competitive world is filled with so many stressful situations that they are constantly appraising situations as threatening to their psychological survival and thus giving their bodies little chance to relax (Sapolsky, 2002). The result, as shown in the figure above, is that the constant use of threat appraisals continually triggers the fight-flight response. In turn, the fight-flight response produces a heightened state of physiological arousal that goes on and on and thus increases the risk of developing one or more ***psychosomatic symptoms*** (Kemeny, 2003).

We'll discuss different kinds of psychosomatic symptoms as well as why you may develop one symptom but not others.

Development of Symptoms

Do you have any of these symptoms?

Doctors estimate that 60–90% of patients seen in general medical practice have stress-related, psychosomatic symptoms (H. Benson, 2008). For example, patients who had developed psychosomatic symptoms reported that they had experienced a serious stressor (breakup of a relationship, family member leaving home) during the previous six months (Creed, 1993). Some of the more common stress-related or psychosomatic symptoms are listed below. Our students (and each of us) usually report having developed at least one of these psychosomatic symptoms each semester.

Common Psychosomatic Symptoms

- **Stomach symptoms:** feelings of discomfort, pain, pressure, or acidity
- **Muscle pain and tension:** occurring in neck, shoulders, and back
- **Fatigue:** feeling tired or exhausted without doing physical activity
- **Headaches:** having either tension or migraine headaches
- **Intestinal difficulties:** having either constipation or diarrhea
- **Skin disorders:** exaggerated skin blemishes, pimples, oiliness
- **Eating problems:** feeling compelled to eat or having no appetite
- **Insomnia:** being unable to get to sleep or stay asleep
- **Asthmatic or allergic problems:** worsening of problems
- **High blood pressure or heart pounding**
- **Weak immune system and increased chances of getting a cold or flu**

Development of Psychosomatic Symptoms

Researchers find that whether one develops a psychosomatic symptom as well as the kind of symptom depends upon several different factors.

Genetic predisposition. Because of genetic predispositions, most of us inherit a tendency that targets a particular organ or bodily system for weakening or breaking down, such as the heart, blood vessels, stomach lining, or immune system. That's why different individuals who are in similar stressful situations experience different kinds of psychosomatic symptoms. For example, researchers found that some individuals inherit genes that protect their bodies from potentially harmful hormonal effects produced by frequent activation of the fight-flight response. As a result, these individuals may experience fewer psychosomatic symptoms (van Rossum et al., 2002).

Lifestyle. Some lifestyles, such as smoking, being overweight, not exercising, or taking little time for relaxing, promote poor health practices. Such lifestyles give the body little chance to relax and recover from the heightened state of physiological arousal that is produced when the fight-flight response is triggered.

Threat appraisals. Some of us are more likely to appraise situations as threatening, thus eliciting negative emotions, which automatically trigger the fight-flight response (Kiecolt-Glaser et al., 2002). One solution (discussed in the Application section) is to practice changing threat appraisals, which involve negative emotions, into challenge appraisals, which involve positive emotions (N. Skinner & Brewer, 2002).

But how can worrying cause my awful stomach pains?

Psychosomatic symptoms. The development of psychosomatic problems comes from poor lifestyles and too many threat appraisals, which in turn trigger many fight-flight responses, which can damage or break down body organs that may have already been weakened by genetic factors (Kemeny, 2003). Later we'll discuss how to prevent psychosomatic problems by developing an effective stress management programs.

Next, we'll examine in more detail how prolonged stressful experiences can affect and break down the body organs.

General Adaptation Syndrome

What does stress do?

One thing continued stress does is activate the fight-flight response. The continual activation of fight-flight responses results in what Hans Selye (1993) has described as the general adaptation syndrome.

The ***general adaptation syndrome*** (GAS) refers to the body's reaction to stressful situations during which it goes through a series of three stages—alarm, resistance, and exhaustion—that gradually increase the chances of developing psychosomatic symptoms.

Selye's general adaptation syndrome explains how coed Joan, who felt continually overwhelmed, developed a psychosomatic symptom, stomach pain.

During stress, the body goes through 3 stages.

1 *Alarm Stage*

Alarm: initial reaction

As sleep-deprived Joan worries about having too little time for all she has to do, she appraises that situation as a terrible threat to her well-being, which causes her body to be in the alarm stage.

The ***alarm stage*** is the initial reaction to stress and is marked by activation of the fight-flight response; in turn, the fight-flight response causes physiological arousal.

Your body may go into and out of the alarm stage (fight-flight response) many times during the day as stressful experiences come and go. Normally, you do not develop psychosomatic problems during the alarm stage because the fight-flight responses come and go. However, if stress continues for a longer period of time, your body goes into the resistance stage.

2 *Resistance Stage*

Resistance: fighting back

As the semester comes to an end, Joan's continual feelings of being overwhelmed cause almost continual fight-flight responses, which in turn cause her body to go into the resistance stage.

The ***resistance stage*** is the body's reaction to continued stress during which most of the physiological responses return to normal levels but the body uses up great stores of energy.

During the resistance stage, Joan's body will use up vital reserves of hormones, minerals, and glucose (blood sugar) because her body is almost continually in the fight-flight state. Joan doesn't realize that the resistance stage is taking a toll on her stomach by interfering with digestion and causing stomach pain, a psychosomatic symptom. If her stress continues, her body will go into the exhaustion stage and her psychosomatic symptom will worsen.

3 *Exhaustion Stage*

Exhaustion: breakdown in organs

As Joan's feeling of being overwhelmed continues over many weeks, her body may enter the exhaustion stage.

The ***exhaustion stage*** is the body's reaction to long-term, continuous stress and is marked by actual breakdown in internal organs or weakening of the infection-fighting immune system.

During the exhaustion stage, Joan's stomach problems may become more serious. Extended periods of stress, such as during final exams, may cause your body to go into the stage of resistance or exhaustion. During this time you may develop a variety of psychosomatic symptoms, such as a cold, flu, cold sore, sore throat, allergy attack, aching muscles, or stomach problems. For example, researchers found that individuals who had prolonged and high levels of anxiety, signaling stages of resistance and exhaustion, were more likely to develop physical health problems than those with normal levels (C. W. Hoge et al., 2007). As you'll see, psychosomatic symptoms develop because of a mind-body interaction.

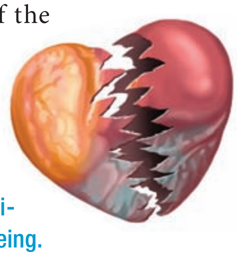
Mind-Body Connection

Can your mind cause health problems?

At the beginning of this module, we learned how Luisa's mind can intensify the physical sensations she feels during a panic attack. This is a perfect example of the mind-body connection.



The ***mind-body connection*** refers to how your thoughts, beliefs, and emotions can produce physiological changes that may be either beneficial or detrimental to your health and well-being.

For example, the mind-body connection explains why, after a prolonged period of fearful or anxious thoughts that continually trigger the fight-flight response, there may be a breakdown in body organs and development of psychosomatic symptoms (C. W. Hoge et al., 2007). Researchers found that emotional stress, such as hearing the news of a death in the family, narrowly avoiding a car accident, or walking into a surprise party, can trigger a condition that mimics a massive heart attack. Doctors call this condition "broken-heart syndrome" and explain that when patients experience emotional shock, a sudden surge of stress hormones is released, overwhelming the heart. After the emotional stress subsides, the stress hormone levels return to normal and the heart functions properly again (Fackelmann, 2005).

Research on the importance and implications of the mind-body connection has given rise to mind-body therapy (Goleman & Gurin, 1993).

Mind-body therapy is based on the finding that thoughts and emotions can change physiological and immune responses. Mind-body therapy uses mental strategies, such as relaxation, meditation, and biofeedback, as well as social support groups to help individuals change negative beliefs, thoughts, and emotions into more positive ones.

Currently, about 17% of adults in the United States use mind-body therapy. Mind-body therapy can be effective in treating many different physical problems, including headaches, back and neck pain, multiple sclerosis, and ADHD (Bertisch et al., 2009; Sierpina et al., 2007; Wahbeh et al., 2008). At the end of this module, we'll discuss specific mind-body therapies, called stress management programs, that help people recognize and deal with stress overload and thus prevent or reduce psychosomatic symptoms.

The mind-body connection is involved in the prevention as well as the development and maintenance of psychosomatic symptoms. More unexpectedly, the mind-body connection is involved in the strengthening or weakening of our immune systems, which is the next topic.

B. Physiological Responses

Immune System

Why did you get a cold?

How often have you gotten a cold, strep throat, or some other bacterial or viral infection when final exams were over? This rather common experience of "coming down with something" when exams are over indicates how prolonged stressful experiences can decrease the effectiveness of your immune system.

The ***immune system*** is the body's defense and surveillance network of cells and chemicals that fight off bacteria, viruses, and other foreign or toxic substances.

Getting a cold is partly due to how much stress you're under.

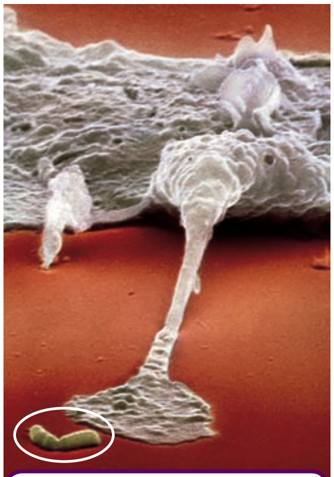
For many years, researchers believed that the immune system was a totally independent bodily system with no input from the brain and certainly not influenced by one's thoughts. However, in the mid-1970s, a psychologist and an immunologist found the first good evidence of a mind-body connection—that psychological factors, such as one's thoughts, influenced the immune system (R. Ader & Cohen, 1975). Their research led to the development of an entirely new area of medical science that is called psychoneuroimmunology *(SIGH-ko-NOOR-oh-im-you-NAH-luh-gee),* which is an example of the mind-body connection.

Psychoneuroimmunology

Researchers Ader and Cohen (1975) were trying to figure out why some of their rats were dying so young when they chanced upon one of the important scientific discoveries of the 1970s. Previously, immunologists believed the immune system operated independently of psychological influences. Then, to the surprise of all and the disbelief of many, Ader and Cohen reported that psychological factors influenced the immune system's functioning. Today, no one doubts their findings, which launched the field of psychoneuroimmunology (R. Ader, 2007).

Psychoneuroimmunology is the study of the relationship among three factors: the central nervous system (brain and spinal cord), the endocrine system (network of glands that secrete hormones), and psychosocial factors (stressful thoughts, personality traits, and social influences).

For example, coming down with an illness (cold, flu) after a stressful time results from the interactions among three factors—central nervous system, endocrine system, and psychosocial factors. These three factors can suppress or strengthen the immune system and in turn make the body more or less susceptible to disease and infection (Kiecolt-Glaser et al., 2002). For instance, when stress weakens the immune system, it can reduce the number of natural killer cells known to fight cancer (Lenzer, 2007). Also, when elderly people lose their spouse, the bereavement process can take a serious toll on their body leading to a 53–61% increased risk of death within one month (Christakis & Allison, 2006). As you can see, the effects of stress on the body can be very profound.



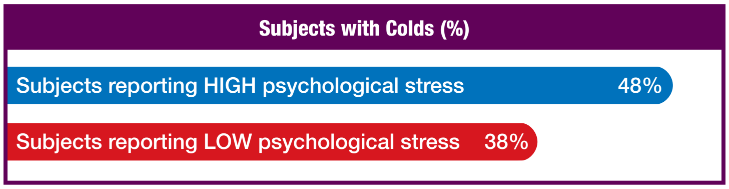
An immune system cell sends out a footlike extension to destroy a bacterial cell (in white oval).

The immune system has several ways to kill foreign invaders. In the left photo, an immune system cell sends out a footlike extension to engulf and destroy the small green bacterial cell (inside the white oval).

However, the immune system's defenses can be weakened by psychosocial factors (R. Ader, 2007).

Evidence for Psychoneuroimmunology

Researchers were faced with a difficult question: Why doesn't everyone who is exposed to a disease virus or bacteria actually get the disease? They tackled this question by giving the same amount of cold virus to 394 subjects, all of whom were quarantined for a week. During this period, the researchers checked for symptoms of colds and related the percentage of colds to the levels of stress that subjects had reported before they received the virus. As shown in the graph below, researchers found that those individuals who reported high levels of psychological stress were more likely to develop colds than were those who reported low stress levels. Researchers concluded that, with every increase in psychological stress, there's an increased likelihood of developing a cold—provided we are exposed to the cold virus (S. Cohen, 2003; S. Cohen et al., 1997).



Fight-flight response. While short-term stress (such as exam stress or traffic) can weaken the immune system, chronic stress (such as relationship conflict or unemployment) has even more severe effects on our health (Segerstrom & Miller, 2004). People who experience chronic stress are more prone to illness because they are continually activating their fight-flight response. When the fight-flight response is activated, your body produces stress hormones, which suppress the immune system and make the body more susceptible to diseases, viruses, and other infections, as well as reduce its ability to heal from wounds and respond to vaccinations (Ebrecht et al., 2004; Kiecolt-Glaser, 2008). One psychoneuroimmunology researcher described the effects of chronic stress on the body by saying, "Stress made 55-year-olds have 90-year-old immune systems" (Kiecolt-Glaser, 2008).

Conclusion. Since the 1970s, the field of psychoneuroimmunology has made significant advances. Still, further research is needed to better understand the relationships among the brain, hormones, and psychological factors (Bonneau et al., 2007).

How psychological factors affect the immune system will become clearer as we next describe a really clever experiment.

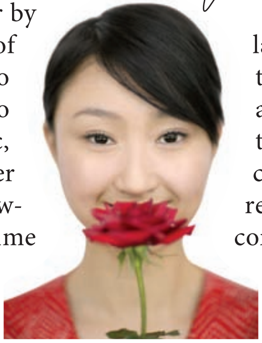
Conditioning the Immune System

Could artificial flowers make you sneeze?

There is an interesting story of a woman who was in therapy for having severe allergic reactions to flowers. The therapist was curious about what caused her allergic reaction. It could be caused either by organic factors, which refer to the physical properties of flowers, or by psychosomatic factors, which refer to thoughts, beliefs, or conditioned responses to flowers. To determine whether the cause was organic or psychosomatic, one day the therapist took a dozen red roses from under her desk, gave them to the woman, and asked her what the flowers reminded her of. The woman held them for a short time and then began to have allergic responses, including nasal congestion and tears. What the woman did not know was that the flowers were artificial.



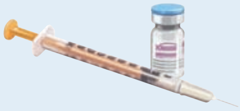
Why do artificial flowers make my nose run?

The woman's allergic reaction to artificial flowers clearly demonstrated that the cause of her allergy was not physical but psychosomatic (caused by the woman's own thoughts). As the woman later explained, her husband had regularly given her flowers as a sign of affection, but now that he was seeking a divorce, the flowers had become a depressing or aversive stimulus. This means that, through classical conditioning, flowers had become conditioned stimuli capable of eliciting a conditioned response—in this case, an allergic reaction (classical conditioning is discussed on pages 197–199). Just to be sure, researchers designed the following experiment that left no doubt that the immune system could be classically conditioned (Maier et al., 1994).

Classical Conditioning Experiment

If the immune system could be classically conditioned, it would clearly show the influence of psychological factors. As explained in Module 9, classical conditioning involves changing a neutral stimulus, such as a flashing light or a humming fan, into a conditioned stimulus so that it alone can elicit a conditioned response—in this case, an allergic reaction in a rat. Here's how an immune response (allergic reaction) was classically conditioned in rats (MacQueen et al., 1989).

Conditioned stimuli: flashing light and humming fan.



Unconditioned stimulus: injection of a substance that produces allergy.

Unconditioned response: allergic reaction elicited by injected substance.

1 For the first three trials, each rat was first presented with two conditioned (neutral) stimuli, a light flashing and a fan humming. A short time later, each rat was given an injection of an allergy-producing substance, which was the unconditioned stimulus. In turn, the unconditioned stimulus elicited an allergic reaction, which was the unconditioned response.

2 On the fourth trial, the animals were divided into two groups: control and experimental groups.

Control group received a trial with the regular sequence: flashing light and fan humming, then the injection of the substance, which elicited the allergic reaction.

Experimental group of rats received a different trial: Rats were exposed only to the conditioned stimuli of flashing light and fan humming, with no injection.

3 The ***experimental group*** of animals showed a conditioned response, which means that just being given or exposed to the conditioned stimuli (flashing light and humming fan) caused the allergic reaction, which is the ***conditioned response.***

4 **Discussion.** During classical conditioning, animals or people learn that the neutral or conditioned stimulus signals or predicts what will happen next. In this study, rats learned that the flashing light and humming fan predicted an allergic reaction. And in fact, by the fourth trial, the conditioned stimuli (light and fan) alone elicited the allergic reaction—the conditioned response. Researchers concluded that psychological factors can trigger an allergic reaction in animals (MacQueen et al., 1989).

5 **Conclusion.** The amazing fact that immune responses can be conditioned demonstrates a method through which purely psychological or cognitive factors can affect immune function. Although the immune system was originally thought to act independently, it is now known that psychological factors influence the immune system in both animals and humans (F. Ader, 1999).

These findings in rats explain why the woman had an allergic reaction to artificial flowers: The artificial flowers had become conditioned stimuli that, by themselves, could elicit conditioned responses—in this case, allergic reactions of congestion and tearing eyes.

The history of psychoneuroimmunology reads like a mystery story. For 50 years, researchers had written in stone that the immune system was totally independent and only a fool would believe otherwise. In the early 1970s, Ader the psychologist and Cohen the immunologist were studying something entirely different (why animals were dying prematurely) when they discovered the reason was that the animals' immune systems had been weakened through classical conditioning (R. Ader & Cohen, 1975). This revolutionary finding meant the immune system could be influenced by psychological factors, and this led to the birth of a whole new field, called psychoneuroimmunology (F. Ader, 1999).

We have discussed how stressful experiences trigger the fight-flight response and affect the immune system. Next, we'll examine which situations are the most likely to become stressful.

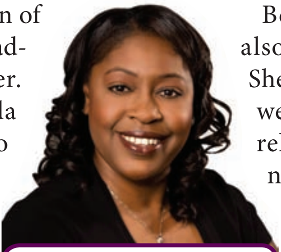
C. Stressful Experiences

Kinds of Stressors

What are Brenda's stressors?

We began this module with a description of Brenda's busy day as a single mother, graduate school student, and school teacher. There are countless daily hassles Brenda encounters: managing to be on time to her job and classes, completing her homework and studying, cooking, cleaning, getting her son through the many steps of his day, and managing the behavior of the children in her classroom, to list just a few. Hassles are small stressors, which can add up to make what she would probably call a "bad day."



Brenda has dozens of hassles and had several major life changes.

Besides dealing with daily hassles, Brenda has also gone through a number of major life changes: She quit using drugs, became a single mother, and went back to college. Unlike hassles, which seem relatively small, major life events have had a significant impact on Brenda's life and can be very big stressors.

Both hassles and major life events have the potential to become stressful experiences that influence mood and the development of psychosomatic problems.

Hassles

When someone asks, "And how was your day?" you usually reply with a list of hassles.

Hassles **are those small, irritating, frustrating events that we face daily and that we usually appraise or interpret as stressful experiences.**

For example, a nationwide survey of adults (ages 25–74) found that the most frequently reported daily hassles involved interpersonal tensions followed by work-related stressors. The most frequently reported appraisals involved danger (36%), loss (30%), or frustration (27%), and only 2% were appraised as representing opportunity or challenge. Generally, women reported the stressors as being more severe than did men. As the number of daily hassles increased, so too did the chance of developing psychosomatic problems or being in a bad mood (Almeida et al., 2002).

Daily hassles are related to having physical problems.

The opposite of a hassle is a good experience called an uplift.

Uplifts **are those small, pleasurable, happy, and satisfying experiences that we have in our daily lives.**

For many college students (and most adults), the daily hassles, which lead to having a "bad day," usually far outnumber the uplifts, which lead to having a "good day." For example, how often do you hear people say, "I had such a great day!" In contrast to hassles, daily uplifts are associated with less depression and better functioning (Macnee & McCabe, 2000).

Besides hassles, another source of stress involves major life events.

Major Life Events

Experiencing a major life event (getting married) can be stressful.

Not only do hassles increase stress levels and predict daily mood and health, but so do major life events.

Major life events **are potentially disturbing, troubling, or disruptive situations, both positive and negative, that we appraise as having a significant impact on our lives.**

Researchers measure life events using the Social Readjustment Rating Scale (below) (M. A. Miller & Rahe, 1997). The number after each event rates the impact that the event would have on one's life; death of one's spouse has the highest rating (119). To obtain your score, add the numbers associated with each event you have experienced in the last year. The total reflects how much life change you have experienced. Researchers predicted that experiencing an increased number of life changes would increase levels of stress and, in turn, increase the chances of developing psychosomatic problems.

In the scale at the right, events in a six-month period that total over 300 and events in a one-year period that total over 500 indicate high life stress and an increased risk of developing psychosomatic problems (M. A. Miller & Rahe, 1997).

One problem with the Social Readjustment Rating Scale is that it makes no distinction between appraisals of positive events (getting married) and negative events (getting divorced). More recent scales found that the appraisal of negative life events was more important in predicting illnesses or depression than were positive events (Dixon & Reid, 2000; Shimizu & Pelham, 2004).

Adjustment Disorder. As we just learned, major life events, such as getting married, moving, beginning college, and losing a job, can cause stress. Most of the time, people adjust to these changes within a few weeks or months. However, in some cases, these life changes may cause people to feel anxious or depressed for many months, which means they have adjustment disorder.

Adjustment disorder **is a condition in which a person is unable to cope with or adjust to a major life change. The condition includes emotional (such as feeling depressed, overwhelmed) and behavioral (such as avoiding social interaction, performing poorly at school or work, making reckless decisions) symptoms.**

Individuals with adjustment disorder experience an excessive reaction to a life stressor, and their symptoms cause trouble in their daily functioning.

Next, we'll discuss how stressful events are generally frustrating experiences.

Social Readjustment Rating Scale

Life event	Mean value
Death of spouse	119
Divorce	98
Death of close family member	92
Fired at work	79
Personal injury or illness	77
Death of a close friend	70
Pregnancy	66
Change in financial state	56
Change in work conditions	51
Marriage	50
Sex difficulties	45
Change in living conditions	42
Change in residence	41
Beginning or ending school	38
Great personal achievement	37
Change in school	35
Trouble with boss	29
Revision of personal habits	27
Change in sleeping habits	26
Vacation	25
Minor violations of the law	22

Situational Stressors

What makes situations stressful?

We're going to examine three situations—being frustrated, feeling burned out, and experiencing interpersonal violence—that have the potential to be highly stressful. What can make these situations especially stressful is they can all elicit very negative emotions, which can greatly increase levels of stress.

Frustration

Being a pop music star is exhausting.

Several years ago, Mariah Carey (left photo), a Grammy-winning singer who has sold tens of millions of albums, cancelled all of her public appearances and checked herself into a hospital, complaining of "extreme exhaustion." She felt tremendous stress resulting from completing two movies while writing, recording, and producing an album ("Mariah in hospital," 2001). Mariah Carey's example illustrates the difficulties of having a job in which success is judged by how many albums you sell or the number of Grammy awards you win. Having low album sales or not winning an award can be very frustrating.

***Frustration* is the awful feeling that results when your attempts to reach some goal are blocked.**

You may be blocked from reaching a goal because of ***personal limitations,*** such as losing your temper, making dumb mistakes on an exam, or not having the skills to pass a course. Or you may be blocked from reaching a goal because of ***social*** or ***environmental limitations,*** such as having to work 18-hour days. One reason frustrating situations are especially stressful is that they seem to be beyond your control and they usually elicit strong negative emotions, such as anger or rage (Goldberger & Breznitz, 1993).

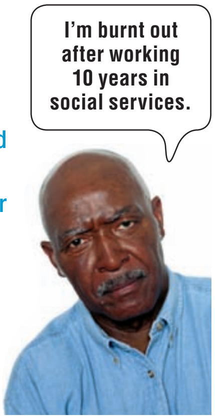
Monday versus Friday. One survey found that compared to Fridays, Mondays were more stressful and frustrating because of having to return to work, having too many things to do, not having enough time, and expecting but not getting as much done. The stress and frustration experienced on Mondays resulted in 33% more heart attacks than occurred on Fridays (Friend, 1994). This is an example of how stress and frustration can contribute to dangerous psychosomatic problems.

If frustration lasts for a long period of time, the result can be burnout.

Burnout

About 5% to 20% of nurses, lawyers, police officers, social workers, managers, counselors, teachers, medical residents, and others whose jobs demand intense involvement with people suffer from burnout (Farber, 2000a, 2000b).

***Burnout* refers to being physically overwhelmed and exhausted, finding the job unrewarding and becoming cynical or detached, and developing a strong sense of ineffectiveness and lack of accomplishment in this particular job (Maslach, 2003).**



I'm burnt out after working 10 years in social services.

Burnout is accompanied by intense feelings and negative emotions that trigger the fight-flight response, keep the body in a continual state of heightened physiological arousal, and cause most of the psychosomatic symptoms we have discussed: sleep problems, stomach disorders, headaches, muscle pain (especially lower back and neck), and frequent and prolonged colds (Melamed et al., 2006).

One way to reduce the likelihood of burnout is to take a vacation. Research shows that time spent on vacation enhances people's well-being by decreasing their complaints about health problems and exhaustion (C. Fritz & Sonnentag, 2006).

Student burnout. College counselors report that burnout often causes students to drop out of college. Counselors suggest that before students decide to drop out, they should consider ways to reduce their work and class load so that school seems less overwhelming and more manageable (Schaufeli et al., 2002).

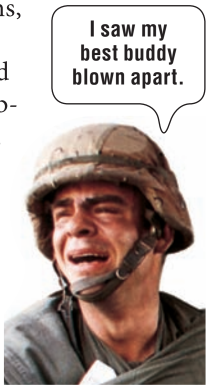
The next situation is so stressful that it leaves a terrible, lasting mark that may trigger years of problems.

Violence

Most people experience at least one traumatic situation during their life. About 30% to 50% of children experience at least one traumatic event before they reach 18 (Kazdin, 2008). For some people the experience is so stressful it results in posttraumatic stress disorder (E. J. Ozer et al., 2003).

***Posttraumatic stress disorder,* or *PTSD,* is a disabling condition that results from personally experiencing an event that involves actual or threatened death or serious injury or from witnessing or hearing of such an event happening to a family member or close friend. People suffering from PTSD experience a number of psychological symptoms, including recurring and disturbing memories, terrible nightmares, and intense fear and anxiety (APA, 2000).**

For example, about 32% of women report having PTSD after being raped; about 15% of soldiers report having PTSD after serving in war; and about 20% of people report having PTSD after being in a serious car accident (Elias, 2008a; Hidalgo & Davidson, 2000). These horrible memories and feelings of fear keep stress levels high and result in a range of psychosomatic symptoms, including sleep problems, pounding heart, high blood pressure, and stomach problems (Marshall et al., 2006; Schnurr et al., 2002).



I saw my best buddy blown apart.

Treatment. The treatment of posttraumatic stress disorder may involve drugs (SSRIs—p. 534), but some form of cognitive-behavioral therapy (p. 568) has proved more effective in the long term (Bolton et al., 2004). Cognitive-behavioral therapy provides emotional support so victims can begin the healing process, helps to slowly eliminate the horrible memories by bringing out the details of the experience, and gradually replaces the feeling of fear with a sense of courage to go on with life (Harvey et al., 2003; Resick et al., 2008).

We'll examine two more situations with high potential for stress because they involve conflict or anxiety.

C. Stressful Experiences

Conflict

Why are decisions so stressful?

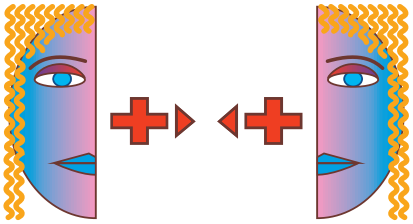
Sometimes situations can be stressful because they involve making difficult decisions. For example, what decisions would you make in the following situations?

- You can either go to a great party or see a good friend who is visiting town for just one day.
- You can study for a psychology exam or write a paper for a history class.
- You can ask a new acquaintance to have lunch, but then you risk being rejected.

In making these kinds of decisions, you are most likely to feel stressed because each involves facing a different kind of conflict.

Conflict is the feeling you experience when you must choose between two or more incompatible possibilities or options.

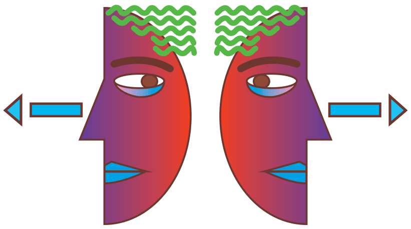
The reason the situations put you in conflict is that, no matter which option you choose, you must give up something you really want to get or you must do something you really want to avoid. We'll describe three common kinds of conflicts—approach-approach, avoidance-avoidance, and approach-avoidance—and some of the ways of dealing with conflicts.



Approach-approach. Deciding between going to a party or seeing a friend involves choosing between two pleasurable options.

Approach-approach conflict involves choosing between two situations that both have pleasurable consequences.

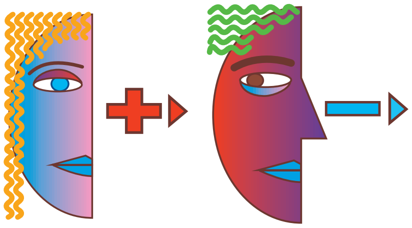
At first it seems that approach-approach conflicts are the least stressful of the three kinds because, whichever option you choose, you will experience a pleasurable consequence. But on second thought, approach-approach conflicts can be the most stressful because you must give up one of the very pleasurable consequences. The result is that you will feel considerably stressed as you agonize over which one of the two great possibilities to give up.



Avoidance-avoidance. Deciding between studying for a psychology exam or writing a paper for a history class involves choosing between two undesirable options.

Avoidance-avoidance conflict involves choosing between two situations that both have disagreeable consequences.

In an avoidance-avoidance conflict, you may change your mind many times and wait until the last possible minute before making the final decision. You delay choosing as long as possible in trying to avoid the disagreeable or unpleasant outcome.



Approach-avoidance. Deciding about asking a new acquaintance to lunch and being afraid of being rejected involves a single situation that has both desirable and undesirable possibilities.

Approach-avoidance conflict involves a single situation that has both pleasurable and disagreeable aspects.

In this example, asking the person to lunch would make you feel good, but at the same time, being rejected is something you want to avoid because it makes you feel bad. Our lives are full of approach-avoidance conflicts, and trying to decide what to do about them can be very stressful.

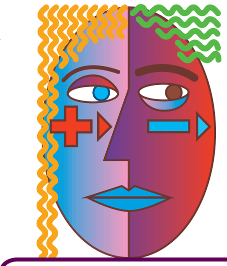
Five Styles of Dealing with Conflict

Researchers have identified five different styles of dealing with conflict, one of which may be similar to yours and one of which is better than the rest (R. J. Sternberg & Soriano, 1984).

1. Avoidance. These individuals find dealing with conflicts unpleasant. They hope that by avoiding or ignoring the conflict it will disappear or magically go away. Sadly, the conflict usually gets worse and will have to be dealt with eventually.

2. Accommodation. These individuals also hate conflicts and just give in to make the disagreement go away. They tend to please people and worry about approval. Unfortunately, giving in does not solve the problem, which in the long term will need to be solved.

3. Domination. In conflicts, these individuals go to any lengths to win, even if it means being aggressive and manipulative. However, aggressively solving conflicts results in hostility rather than intimate human relationships.



What is the best way to settle conflicts?

4. Compromise. These individuals recognize that others have different needs and try to solve conflicts through compromise. Unfortunately, they may use manipulation and misrepresentation to further their own goals, so compromise isn't always the best solution.

5. Integration. These individuals try to resolve conflicts by finding solutions to please both partners. They don't criticize the other person, they try to be open, and they emphasize similarities rather than differences.

Perhaps the best way to resolve relationship conflicts is to try to be as much of an integrator as possible because this style avoids criticism and has the best chance of pleasing both individuals (B. K. Williams & Knight, 1994).

Situations involving conflict can be very stressful because you must often make undesirable choices. The next situations are stressful because they involve anxiety.

Anxiety

How does anxiety develop?

This module began with the story of Luisa, who experienced tremendous anxiety. Remember, Luisa would have sudden and intense panic attacks for no apparent reason. Like Luisa's experiences, everyone at some time will be caught in the terrible grip of anxiety.

Anxiety **is an unpleasant state characterized by feelings of uneasiness and apprehension as well as increased physiological arousal, such as increased heart rate and blood pressure.**

Next, we'll learn three ways of developing anxiety: classical conditioning, observational learning, and unconscious conflict. We'll begin by sharing two personal stories about how each of us developed severe anxiety.

Classical Conditioning

I developed anxiety through classical conditioning.

I (R. P.) have a great fear of blood, which is a result of a traumatic childhood incident: I had seen my father almost cut off his thumb. For me and about 76% of people surveyed, fear of blood began with a traumatic event that involved classical conditioning (Kleinknecht, 1994). In my case, the neutral stimulus was the sight of blood. It was paired with an unconditioned stimulus—seeing my father almost cut off his thumb—that caused an unconditioned response—anxiety, fear, and the fight-flight response. After this single pairing, the sight of blood became the conditioned stimulus, which now elicits the unconditioned response—great anxiety. My fear of blood is an example of a conditioned emotional response.

A ***conditioned emotional response*** **results when an emotional response, such as fear or anxiety, is classically conditioned to a previously neutral stimulus.**

A conditioned emotional response not only is highly resistant to extinction but can also cause stressful feelings (p. 201).

Observational Learning

When I (H. K.) was younger, I had a debilitating fear of public speaking, which came from watching some of my classmates give a speech only to be ridiculed when they made an error. My anxiety developed through observational learning in the classroom.

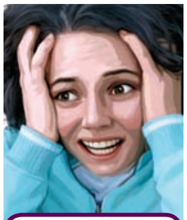
Observational learning, **which is a form of cognitive learning, results from watching and modeling and does not require the observer to perform any observable behavior or receive a reinforcer.**

My observations of classmates speaking in front of the class made me develop severe anxiety over public speaking. Since childhood, I've had to speak in public many times and my anxiety has decreased because I've had positive experiences giving speeches.

I developed anxiety from observing students get embarrassed.

Albert Bandura (2001b) believes the majority of human learning, including feeling anxious in specific situations, occurs through observational learning (p. 225).

Unconscious Conflict



Luisa developed anxiety through unconscious conflict.

During psychotherapy, Luisa discovered the reason for her anxiety was that she was giving up her lifelong dream of becoming a writer to respect her parents' wish for her to become a scientist.

Sigmund Freud hypothesized that there are three divisions of the mind—id, ego, and superego—that at times may be in conflict over how a need should be satisfied (p. 436). This unconscious conflict may result in feeling anxiety.

Anxiety, **according to Freud, arises when there is an unconscious conflict between the id's and superego's desires regarding how to satisfy a need, with the ego caught in the middle. The ego's solution to this conflict is to create a feeling of anxiety.**

According to Freud, we may try to decrease our anxiety by using a number of ***defense mechanisms.*** Luisa had been using the defense mechanism of repression to help manage her anxiety, but this did not solve her dilemma of which career to choose. As a result, her anxiety intensified and she began having panic attacks.

Next, we'll learn about different ways stress can actually be positive.

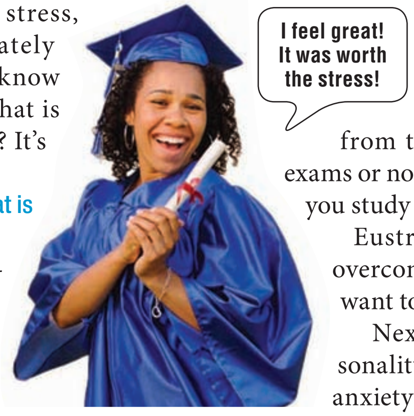
Positive Stress

How can stress be positive?

When most people think of stress, negative thoughts immediately come to mind. But, did you know that there is a type of stress that is actually healthy and desirable? It's called eustress.

Eustress **is a pleasant and desirable type of stress that is healthful and keeps us engaged in situations.**

You've likely experienced eustress when purchasing a new car, applying to college, getting a promotion at work, winning first place in a competition, watching a suspenseful thriller, getting married, or having a child.



I feel great! It was worth the stress!

As a student, you can probably acknowledge that a little bit of stress in school helps motivate you to study. Just imagine if your instructor removed all of the potential stress from the course, such as not requiring you to take exams or not assigning grades! Be honest—how much would you study then?

Eustress arouses and motivates us to achieve and overcome challenges. It is one type of stress we don't want to live without.

Next, we'll examine how different kinds of personality variables can help or hinder our coping with anxiety and stress.

D. Personality & Social Factors

Hardiness

How does he cope with the stress of competition?

Shaun White, nicknamed the "Flying Tomato" for his long, curly red hair, has never been an ordinary athlete. At the age of 6, he began skateboarding on a ramp in his backyard, and he practiced snowboarding during family trips to the mountains. By the time Shaun was 13 years old, he became a pro skateboarder and snowboarder. At age 19, he became the first athlete to compete in both the summer and winter X Games. Shaun always strives to do his very best, even under the most stressful situations. He does not allow the pressure of heated competition or the setback of an awkward landing to compromise his determination to win. Shaun's ability to handle extreme stress became most evident when he won an Olympic gold medal in 2006 (Ruibal, 2006; "Shaun White," 2006).

How can Shaun White, the "Flying Tomato," perform so well in extremely stressful conditions?

Why is it that certain people, like Shaun White, seem to handle stressful situations better than others? This was exactly the question researchers asked as they studied the personality characteristics of middle- and upper-level executives and lawyers who had experienced considerable stress in the past three years (Kobasa, 1982; Kobasa et al., 1982a, 1982b). Researchers discovered that those executives and lawyers who stayed healthy in spite of stressful life situations had three personality traits, which, taken together, were labeled hardiness.

Hardiness **is a combination of three personality traits—control, commitment, and challenge—that protect or buffer us from the potentially harmful effects of stressful situations and reduce our chances of developing psychosomatic illnesses.**

Shaun White is a great example of a hardy person who has the three Cs—control, commitment, and challenge. His disciplined practicing shows he has ***commitment*** to his goal of being a snowboarding legend; his participation in the Olympics shows he likes a ***challenge;*** and his determination to come back more focused after even the slightest error indicates his desire to be in ***control*** (Maddi, 2008).

Just as hardiness helps Shaun White deal with stress, hardiness helps people cope in a wide range of stressful situations, such as nurses who work with dying patients and military personnel who experience life-threatening situations (Bartone, 1999; Maddi, 2002). Researchers also reported that hardiness helps college students cope by reducing the effects of daily frustrations (Beasley et al., 2003). Hardiness is a personality factor that increases protection against stress and decreases the chances of developing psychosomatic symptoms. Being hardy motivates people like Shaun White to see stressors as opportunities for growth, which gives them a real edge in dealing with potentially stressful situations (Bonanno, 2004; Maddi, 2008).

Next, we'll discuss what researchers have learned by studying control, one of the three traits in hardiness.

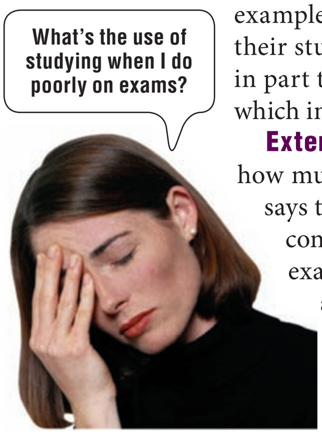
Locus of Control

Why can waiting be such a hassle?

A daily hassle that most of us hate is having to wait for something or somebody. One reason waiting can be so stressful is that we have little or no control in this situation. How much control you feel you have over a situation is a personal belief that is called locus of control.

Locus of control **represents a continuum: At one end is the belief that you are basically in control of life's events and that what you do influences the situation; this belief is called an internal locus of control. At the other end is the belief that chance and luck mostly determine what happens and that you do not have much influence; this belief is called an external locus of control.**

Most of us lie somewhere along the locus of control continuum, rather than being at one end or the other (Carducci, 2006). For example, when students discuss how much their studying affects their grades, they are in part talking about their locus of control, which in turn affects their stress level.

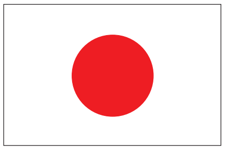


What's the use of studying when I do poorly on exams?

External locus of control. "No matter how much I study, it never seems to help," says the student with an external locus of control. This student will likely appraise exams and papers as less of a challenge and more of a threat, which in turn will generate negative emotions (fear, anxiety, anger) and increase stress levels.

Internal locus of control. "If I study hard and apply myself, I can get good grades," says the student with an internal locus of control. This student will likely appraise exams and papers less as threats and more as challenges, which in turn will generate positive emotions (excitement, enthusiasm) and decrease stress levels. This means that students with internal locus of control have lower levels of stress and, as a result, report fewer psychosomatic symptoms than those with external locus of control (Ruiz-Bueno, 2000).

A cross-cultural study comparing stress and coping styles among Japanese and British people revealed interesting results about stress and a sense of control. Although Japanese people reported feeling less personal control, only British people reported that a feeling of less personal control results in increased stress. These results suggest that a sense of control may be most important in Western cultures that emphasize autonomy and personal accomplishment (O'Connor & Shimizu, 2002).



Studies on locus of control show that our personality traits influence our appraisal (more or less challenging or threatening), which, in turn, increases or decreases our feelings of stress and our chances of developing psychosomatic symptoms (Kirkcaldy et al., 2002).

Another personality trait that can influence stress levels is how pessimistic or optimistic we generally are.

Photo Credits: left, © Joe Klamar/AFP/Getty Images; right, © PhotoDisc, Inc.

Optimism Versus Pessimism

Why is it better to be an optimist?

If you want to experience more positive than negative emotions and reduce your levels of stress, try being more optimistic.

Optimism **is a relatively stable personality trait that leads to believing and expecting that good things will happen.** ***Pessimism*** **is a relatively stable personality trait that leads to believing and expecting that bad things will happen.**

Optimists. One way optimists reduce stress is by focusing on the good things, a process called ***positive reappraisal.*** Forms of positive reappraisal include discovering new opportunities for personal growth, noticing actual personal growth, and seeing how your actions can benefit others. By using positive reappraisal, you can change the meaning or appraisal of situations to seem more positive and thus feel positive emotions (Folkman & Moskowitz, 2000). Researchers found that individuals who perceive themselves as in control—that is, have an internal locus of control—are more likely to have an optimistic attitude in dealing with stressors (C. T. F. Klein & Helweg-Larsen, 2002). Generally, optimists cope more effectively with stress and experience more positive emotions and fewer psychosomatic symptoms than pessimists (Nes & Segerstrom, 2006; S. E. Taylor et al., 2000). Optimists may even live longer than pessimists (DeKeukelaere, 2006; Giltay et al., 2004; R. Rubin, 2009).

"I'm an optimist and believe that good things will happen."

Pessimists. Because pessimists expect bad things to happen, they are likely to change the meaning or appraisal of situations to seem more negative and thus experience more negative emotions, such as anger, rage, fear, or anxiety, and they are less able to ask for or receive social support. For example, researchers found that men with high levels of negative emotions were four times more likely to suffer sudden heart death. In comparison, optimistic patients who received heart transplants reported more positive emotions and dealt better with setbacks than patients with more pessimistic outlooks (Leedham et al., 1995).

"I'm a pessimist and believe that bad things will happen."

Numerous studies associate pessimism and negative emotions with increasing stress levels, decreasing functioning of the immune system, and a wide range of psychosomatic symptoms such as high blood pressure, heart problems, headaches, allergies, and stomach problems (Vahtera et al., 2000).

Personality factors. During the past 10 years, a number of personality factors, such as optimism/pessimism, internal/external locus of control, and hardiness, have been associated with feeling more or less positive or negative emotions, which in turn are involved in increasing or decreasing stress levels and increasing or decreasing the chances of developing psychosomatic symptoms (Salovey et al., 2000).

Next, we'll learn about a new direction in psychology that focuses on better understanding positive attitudes and happiness.

Positive Psychology

Why should I focus more on the positive?

Sherrod Ballentine has a stressful job as a court mediator, and although she's not clinically depressed, she wants to learn ways to improve her mood. She takes a class called "Authentic Happiness and How to Obtain It" and learns activities that will train her mind to focus more on the positive. One activity Sherrod learns is to write down three happy events and their causes at the end of each day for a week. After completing the class, she said, "I am happier. Every day, I feel so grateful to wake up this way" (Lemley, 2006). Sherrod's new learned skills are based on positive psychology.

Positive psychology **is the scientific study of optimal human functioning, focusing on the strengths and virtues that enable individuals and communities to thrive. It aims to better understand the positive, adaptive, and fulfilling aspects of human life.**

Positive psychology has three main concerns. The first is the study of ***positive emotions,*** such as happiness, hope, love, and contentment. The second is the study of ***positive individual traits,*** such as altruism, courage, compassion, and resilience. The third is the study of ***positive institutions,*** or the strengths that promote better communities, such as justice, parenting, tolerance, and teamwork (Seligman, 2003).

One theoretical model states that positive emotions and positive traits enhance health by pushing away negative ones. For instance, it is difficult to be angry or bitter when one is showing compassion and love for others (N. B. Anderson, 2003).

There are many research examples showing that characteristics of positive psychology have a beneficial impact on mood and physical health. For example, a review of research data on altruism and its relationship to mental and physical health found volunteering and other supportive behaviors (such as providing emotional support to others) are associated with higher life satisfaction as well as better physical and mental health (S. Post, 2005). Also, research on writing exercises, such as the one Sherrod did, shows impressive results. One study found that after writing about positive experiences for 20 minutes each day for three consecutive days, college students reported improved mood and had fewer health center visits for illness in the months that followed (C. M. Burton & King, 2004).

Positive psychology has shown us that the benefits of improved mood are endless. For instance, happy people report having more friends, more satisfying marriages, higher incomes, healthier lifestyles, and longer lives than their unhappy peers (Hales, 2008).

One reason there is growing interest in positive psychology is that it provides a change from the tendency of researchers in psychology to focus more on problems or weaknesses than on strengths or virtues.

Next, we'll examine two particular combinations of personality traits that have been labeled Type A and Type D behavior, which have been associated with increasing the chances of having a heart attack.

Photo Credit: bottom left, © PhotoDisc, Inc.

D. Personality & Social Factors

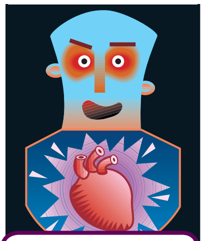
Type A Behavior

Is there such a thing as Type A behavior?

In the mid-1970s, a new expression—"You're a Type A person"—was coined when two doctors published the book *Type A Behavior and Your Heart* (M. Friedman & Rosenman, 1974). At that time, the best-known risk factors associated with developing heart disease were diet, exercise, and smoking. This book startled the medical world by describing a combination of personality traits that made up a psychological risk factor, which was called Type A behavior.

1970s: Type A Behavior—Impatient, Hostile, Workaholic

We'll begin with the original 1970s definition of Type A behavior (M. Friedman & Rosenman, 1974).



Impatient, hostile, and workaholic

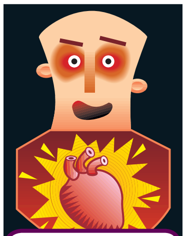
Type A behavior referred to a combination of personality traits that included an overly competitive and aggressive drive to achieve, a hostile attitude when frustrated, a habitual sense of time urgency, a rapid and explosive pattern of speaking, and being a workaholic. ***Type B behavior*** was characterized as being easygoing, calm, relaxed, and patient.

The reason Type A behavior made such a big scientific splash was that, compared to Type B's, Type A's were found to have experienced two to three times as many heart attacks. By 1978, Type A behavior was officially recognized as an independent risk factor for heart disease by a National Institutes of Health panel.

However, at about the same time that Type A behavior was declared a risk factor, researchers began having trouble replicating earlier findings and began to seriously question the definition of Type A behavior.

1980s–1990s: Type A Behavior—Depressed, Angry

Research in the 1980s that showed coronary disease was not associated with being impatient or a workaholic led to both traits being dropped from the new definition of Type A behavior (Booth-Kewley & Friedman, 1987; K. A. Matthews & Haynes, 1986).



Depressed and angry

Type A behavior was defined in the 1980s as being depressed, easily frustrated, anxious, and angry, or some combination of these traits.

Despite using this new and improved definition, a review of many studies between 1983 and 1992 led one researcher to conclude that the relationship between Type A behavior and cardiac disease is so weak as to have no practical meaning and that Type A behavior is no longer a valid or useful concept (Myrtek, 1995). Because of the continuing failure to replicate the original relationship, researchers again redefined Type A behavior.

The 1990s definition of ***Type A behavior*** specifies an individual who feels angry and hostile much of the time but may or may not express these emotions publicly.

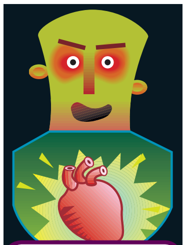
This definition made prolonged hostility or anger (felt or expressed) the major component of Type A behavior (Leventhal & Patrick-Miller, 2000). Research indicates that angry/hostile individuals are three times more likely to have heart attacks, and individuals who are quick to anger under stress are five times more likely to develop a premature heart disease (D. Smith, 2003). Researchers concluded that individuals who either always ***show*** their anger/hostility or always ***suppress*** it have large increases in physiological arousal, which can have damaging effects on one's heart and one's health (Finney, 2003).

Type D Behavior

What is Type D behavior?

2000s: Type D Behavior—Chronic Distress: Negative Affectivity, Social Inhibition

In his work with cardiac patients, Johan Denollet, a psychologist, noticed that some heart-attack survivors remained happy and optimistic, while others became discouraged and pessimistic. He went on to describe a set of behaviors he believed to be predictive of health risk (M. C. Miller, 2005).



Negative affectivity and social inhibition

Type D behavior is defined as chronic distress in terms of two emotional states: negative affectivity (worry, irritability, gloom) and social inhibition (being shy and reserved, lacking self-assurance).

People with Type D behavior tend to experience negative emotions and inhibit self-expression in social interactions. Their chronic distress and lack of strong social support help explain why they are at an increased risk for various health problems (Pelle et al., 2009; L. Williams et al., 2008). For instance, Type D behavior is associated with greater cortisol reactivity to stress and consequently increased risk for coronary artery disease (L. Sher, 2004). Research on patients who had recently received stents to open their coronary arteries showed Type D patients were four times as likely as others to have a heart attack or die within six to nine months of the procedure (M. C. Miller, 2005).

Even though research supports the link between Type D behavior and health problems, recall that research on Type A behavior also began strong, and yet Type A behavior had to be redefined. Type D behavior is a relatively new concept and needs more research to better determine its impact on health conditions (M. C. Miller, 2005).

In conclusion, research on Type A and Type D behavior shows that certain personality traits, such as anger/hostility and negative affectivity/social inhibition, can increase the risks of cardiovascular diseases. This means that treatment for such diseases should include not only medical treatments but also behavioral therapy to decrease negative traits (Merz et al., 2002).

Besides personality factors, social factors affect our stress and health.

Social Support

Do friends help you deal with stress?

We have told you how important findings are often discovered by chance. Here's a "chance" finding that began a new area of research.

In the small town of Roseto, Pennsylvania, people were relatively obese and ate a lot of animal fat. They smoked as much and exercised as little as residents of other neighboring towns. Despite the citizens' awful diet and lifestyle—obvious risk factors for developing heart disease—only one man in 1,000 died of a heart attack, compared with a national rate of 3.5 per 1,000, and the rate for women was even lower. Citizens of Roseto also had lower rates for ulcers and emotional problems compared with rates in the rest of the United States and their neighboring towns.

This puzzling question—why the citizens of Roseto should enjoy such good physical and mental health in the face of obvious risk factors—was answered by a study of the town's social order. "One striking feature did set Roseto apart from its neighbors," says Stewart Wolf, vice president for medical affairs at St. Luke's Hospital in Bethlehem, Pennsylvania, and a principal investigator of the Roseto phenomenon. "We found that family relationships were extremely close and mutually supportive, and this wonderful social support system extended to neighbors and to the community as a whole" (J. Greenberg, 1978, p. 378). But the story of Roseto does not have a happy ending.

As families of Roseto prospered, they moved into larger and finer homes in the countryside, and their social support system began to break down. Families no longer had helpful friends for neighbors, which meant fewer family and friendly get-togethers and far less social support. One of the most interesting and deadly findings was that with the breakdown in social support came an increase in heart attacks, especially in younger men. This study on families in Roseto was one of the first to suggest that dealing with stress and overcoming health risks were in large part aided by one's social support.

We're always helping one another.

Social support reduces stress.

Social support **refers to three factors: having a group or network of family or friends who provide strong social attachments; being able to exchange helpful resources among family or friends; and feeling, or making appraisals, that we have supportive relationships and behaviors.**

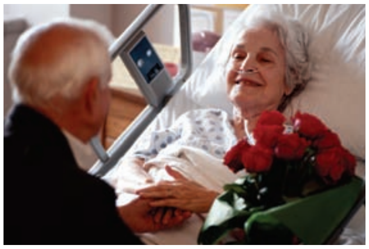
Thirty years ago, no one would have thought that loneliness and lack of social support were major factors that contributed to becoming ill and developing psychosomatic symptoms. Today, social support is reported to be a very important coping method that individuals use to decrease the effects of stressful situations and cope with psychosomatic problems (Uchino, 2004).

Not only has our understanding of the importance of social support moved forward, but so has our ability to provide and receive social support. Anyone with access to the Internet can find support by participating in virtual support groups, which can be effective in helping people cope with stress associated with psychosocial and medical problems (Høybye et al., 2005; Marziali et al., 2006).

We'll present studies that illustrate how social support buffers us from stress and social conflict creates stress.

Buffer against Stress

Many of us have asked for help in solving a variety of problems, which range from feeling lonely to needing to borrow money. In these troublesome situations, social support helps us cope with stress by giving us confidence, raising our self-esteem, and increasing our feelings of self-worth, which in turn promote and maintain psychological adjustment.



For example, cutting-edge research found that married women under extreme stress feel immediate relief upon holding their husband's hand (Carey, 2006). In this study, women were placed in an MRI machine and told they would periodically receive a mild electric shock. Brain scans showed heightened activity in areas involved in physical arousal and anticipating pain. As soon as husbands reached into the machine and touched their wife's hand, the activity levels in all brain areas responding to the stress dropped substantially. It is interesting that, although a stranger's hand resulted in some drop in brain activity in areas responding to stress, the drop was not as substantial as that from the husband's touch. Another similar study, this time focusing on other physiological measures of stress, found that a supportive and caring touch lowers several stress responses, including blood pressure (Holt-Lunstad et al., 2008). From these and other studies on social support and stress, researchers conclude that social support can decrease the effects of stressful experiences (P. D. Martin & Brantley, 2004).

Next, we'll learn how one type of social interaction can actually increase stress.

Social Conflict

Some social interactions can be stressful. In fact, you probably don't have to try very hard to remember a recent conflict you had with a friend, romantic partner, parent, co-worker, or boss. Research indicates that these social conflicts negatively affect physical health. For instance, adults who have conflict in a close relationship experience ongoing stress, which places them at an increased risk of heart problems, weakened immune system, and depression (De Vogli et al., 2007; L. Lyon, 2007).

One way to reduce the effects of social conflict is to have other sources of strong social support. Remember, a good social support system facilitates our maintaining good mental health and protects us from developing illnesses and psychosomatic symptoms (de Grott, 2002; Miyazaki et al., 2003). One of the important functions of a good social support system is to help us develop ways of coping with stress, which we'll discuss after the Concept Review.

Concept Review

1. The cognitive and behavioral efforts that we use to manage a situation that we have appraised as exceeding, straining, or taxing our personal resources are referred to as ________________.

2. Our initial, subjective evaluation of a situation, in which we balance environmental demands against our ability to meet them, is referred to as ________________. We may appraise the situation in three ways: as irrelevant, positive, or stressful.

3. If we appraise a situation as stressful, we go on to determine whether it represents (a) ________________, ________________, or ________________. If our primary appraisal is one of harm/loss or threat, we will experience more (b) ________________ than if our appraisal is one of challenge, because harm/loss or threat appraisals elicit (c) ________________ emotions.

4. A combination of physiological responses that arouse and prepare the body for action is referred to as the (a) ________________ response. This response begins in a part of the brain called the (b) ________________, which triggers the (c) ________________ division of the autonomic nervous system. This response is especially triggered by threat appraisals.

5. Real and painful physical symptoms that are caused by psychological factors, such as our reactions to stress, are called ________________ symptoms.

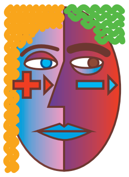
6. A series of three stages—alarm, resistance, and exhaustion—that the body goes through in dealing with stress is referred to as the (a) ________________. The alarm stage is our initial reaction to stress and is marked by activation of the (b) ________________. The resistance stage is the body's reaction to continued stress and is marked by most physiological responses returning to (c) ________________ levels. The exhaustion stage is the body's reaction to long-term, continuous stress and is marked by the actual breakdown or weakening of (d) ________________.

7. The body's defense and surveillance network of cells and chemicals that fight off bacteria, viruses, and other foreign matter is called the ________________ system.

8. The study of how three factors—the central nervous system, the endocrine system, and psychosocial factors—interact to affect the immune system is called ________________.

9. Potentially disturbing, troubling, or disruptive situations—both positive and negative—that we appraise as having considerable impact on our lives are called (a) ________________ events. In comparison, those small, irritating, frustrating events that we face in our daily lives are called (b) ________________, and those small, pleasurable, daily experiences that make us feel happy are called (c) ________________.

10. When our attempts to reach some goal are blocked, the feeling we have is called (a) ________________. The feeling of doing poorly at one's job, physically wearing out, and becoming emotionally exhausted due to intense involvement with people is called (b) ________________. The problem arising from direct personal experience of an event that involves actual or threatened death or serious injury or from witnessing such an event or hearing of such an event happening to a family member or close friend is called (c) ________________.



11. There are three general kinds of conflict. A single situation that has both pleasurable and disagreeable aspects is called (a) ________________ conflict; choosing between two options that both have pleasurable consequences is called (b) ________________ conflict; choosing between two options that both have disagreeable consequences is called (c) ________________ conflict.

12. We can become anxious in at least three different ways. If an emotional response is classically conditioned to a previously neutral stimulus, this procedure results in a (a) ________________ response. If we become anxious through watching and do not perform any observable behavior or receive a reinforcer, this is called (b) ________________ learning. If we become anxious because of unconscious conflicts between the id and the superego, this is (c) ________________ explanation of anxiety.

13. A combination of three personality traits—control, commitment, and challenge—that protect or buffer us from the potentially harmful effects of stressful situations and reduce our chances of developing psychosomatic illness is referred to as (a) ________________. The belief that you are basically in control of life's events and that what you do influences the situation is called an (b) ________________ locus of control. The belief that chance and luck mostly determine what happens is called an (c) ________________ locus of control.

14. If we have family or friends who provide strong social attachments, if we can exchange helpful resources among friends, and if we appraise our relationships as supportive, we would be said to have strong ________________.

Answers: *1. stress or stressful; 2. primary appraisal; 3. (a) harm/loss, threat, challenge, (b) stress, (c) negative; 4. (a) fight-flight, (b) hypothalamus, (c) sympathetic; 5. psychosomatic; 6. (a) general adaptation syndrome, (b) fight-flight response, (c) normal, (d) internal organs or the immune system; 7. immune; 8. psychoneuroimmunology; 9. (a) major life, (b) hassles, (c) uplifts; 10. (a) frustration, (b) burnout, (c) posttraumatic stress disorder; 11. (a) approach-avoidance, (b) approach-approach, (c) avoidance-avoidance; 12. (a) conditioned emotional, (b) observational, (c) Freud's; 13. (a) hardiness, (b) internal, (c) external; 14. social support*

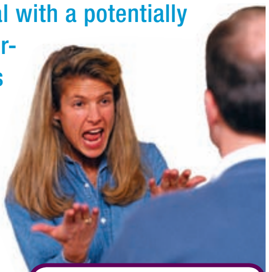
E. Kinds of Coping

Appraisal

Why is arguing stressful?

Sooner or later, every couple gets into an argument. In this case, Susan complained that Bill always got home late, but Bill had had a bad day and said that he didn't want to talk about it. Bill's reply angered Susan, who complained more, which made Bill quieter and madder. One reason Bill and Susan's argument quickly became very stressful was that each one made a ***primary appraisal*** of being threatened, which elicited negative emotions and triggered the fight-flight response, which in turn increased physiological arousal and further intensified their negative feelings. How Bill and Susan deal with their stressful situation depends on what kind of secondary appraisal they make next (Lazarus, 2000).

Secondary appraisal **involves deciding to deal with a potentially stressful situation by using one or both of two different coping patterns: Problem-focused coping means doing something about the particular problem, while emotion-focused coping means dealing with one's negative feelings.**



How can they best end their argument?

Which coping strategy Bill and Susan use to deal with their stressful situation—that is, whether they use problem-focused or emotion-focused coping—will affect how their argument gets resolved and what happens to their levels of stress. We'll discuss how each coping strategy has both short- and long-term disadvantages and advantages.

Kinds of Coping

How to cope with arguing?

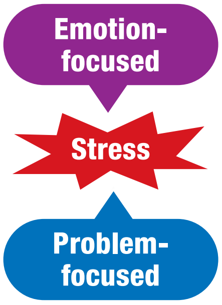
If Bill or Susan tried to decrease the stress by stopping arguing and making up, he or she would be using problem-focused coping.

Problem-focused coping **means we try to decrease stress by solving the problem through seeking information, changing our own behavior, or taking whatever action is needed to resolve the difficulty.**

For example, if Bill agreed to talk about ways of not being late, he would be using problem-focused coping. If Susan agreed to interpret Bill's being late as something he cannot always control and something not to get angry about, she would be using problem-focused coping. The ***goal*** of problem-focused coping is to reduce stress by solving the problem.

Another coping strategy that Bill and Susan might use to decrease stressful feelings is called emotion-focused coping.

Emotion-focused coping **means that we do things primarily to deal with our emotional distress, such as seeking support and sympathy or avoiding or denying the situation.**



These are the two kinds of coping strategies.

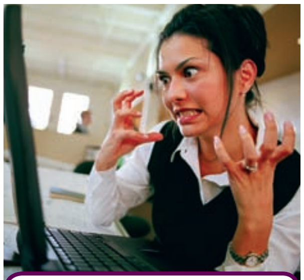
For example, Bill may use emotion-focused coping to get over his anger by going to a sports bar to drink and watch television with the "boys." Susan may use emotion-focused coping to deal with her hurt feelings by calling her friends to talk about what happened and get advice, sympathy, and support.

In the short term, emotion-focused coping may help Bill and Susan deal with their negative emotions, but it doesn't usually solve the basic stressful problem, which means the problem will likely reoccur and cause more stress (Lazarus, 2000). In contrast, a big advantage of using problem-focused coping is that it's a long-term coping strategy, which can help identify and solve the underlying problem that is causing the stressful and negative emotional feelings. In addition, compared to using emotion-focused coping, using problem-focused coping is positively correlated with having and maintaining good physical and mental health (Largo-Wight et al., 2005; Penley et al., 2002).

Choosing a Coping Strategy

Which coping strategy to use?

Which coping strategy you choose depends partly on the situation and on your personality (Lazarus, 2000). For example, one ***personality factor*** that influences whether you use primarily problem-focused or emotion-focused coping is how much ***control*** you believe you have over the situation. If you appraise a situation (being late) as something under your control, you can use primarily problem-focused coping to solve this problem. On the other hand, if you appraise a situation (dealing with your partner's complaints) as being out of your control, you may first use emotion-focused coping to get over your negative emotions (anger). Once you calm down, you can use problem-focused coping to take some direct action to solve the basic problem (being late), which may involve changing some undesirable behavior (being disorganized). The more frustrating a situation is, the more likely you will need to use both emotion-focused coping and problem-focused coping (Lazarus, 2000).



Women and men tend to use different kinds of coping strategies.

Sex differences. Compared with men, women tend to use more coping strategies—problem-focused and emotion-focused—to deal with a wide range of stressors. In addition, compared with men, women are more likely to use emotion-focused coping to seek emotional support and advice from others about dealing with stressors. Compared with women, men are more likely to withdraw or avoid problems and not talk about or engage in emotion-focused coping, especially if problems involve relationship or health concerns (Tamres et al., 2002). Thus, women appear to use more coping strategies and are more willing to talk about solving problems, while men are more likely to keep silent or avoid certain problems.

To deal with stressors, emotion-focused coping is a useful short-term solution. Problem-focused coping is a long-term solution that involves changing our behaviors (Lazarus, 2000).

F. Research Focus: Treatment for Panic Disorder

How Effective Is Treatment for Panic Disorder?

How is panic disorder best treated?

We have discussed stress and coping in general, and now we return to the case of Luisa, the 23-year-old college student with panic disorder. Remember Luisa had unexpected episodes in which she experienced rapid heart rate, a sense of suffocation, trembling of her arms and legs, dizziness, and chest pain. She felt so frightened by these episodes she worried she might die. Luisa's experience of having panic disorder is not uncommon. Many adults suffer from panic disorder, and fortunately there are treatment options available to them. Psychologists conduct research studies to learn which treatment or combination of treatments is most effective for problems such as panic disorder. Next, we'll discover which research methods psychologists use to determine the effectiveness of treatments, as well as discuss research findings on the treatment of panic disorder.

1 Research Methods

In Module 2, we discussed several ways psychologists answer questions, including case studies and experiments, each of which has advantages and disadvantages.

A *case study* is an in-depth analysis of the thoughts, feelings, beliefs, or behaviors of an individual, without much ability to control or manipulate situations or variables.

For example, much of the initial information on how the brain functions came from case studies on individuals who had tumors, gunshot wounds, or accidental damage. Similarly, psychologists can learn about how individuals cope with panic disorder by observing and questioning them as they progress through treatment to identify how they cope and adjust to their condition.

When it is possible to control or manipulate situations or variables, the preferred choice of research method is an experiment.

An *experiment* is a method for identifying cause-and-effect relationships by following a set of guidelines that describe how to control, manipulate, and measure variables, while at the same time minimizing the possibility of error and bias.

Experiments give researchers great control over manipulating treatments and measuring subjects' responses. Also, they allow research data to be collected on a group of people, rather than on only one person, as in a case study, so the results can be more meaningful to a large group of people. Fortunately, psychologists can use experiments to compare the effectiveness of various treatments for panic disorder. We will learn about one such experiment, but before we do, let's learn about the most common treatments available for panic disorder.

2 How Can Panic Disorder Be Treated?

In Luisa's case, her treatment began with medication only, and a few months later she received a combination of medication and psychotherapy. Panic disorder is usually treated with drugs—benzodiazepines (tranquilizers, such as diazepam) or antidepressants (Prozac-like drugs, which are serotonin reuptake inhibitors, or SSRIs)—and/or psychotherapy. Many more people with panic disorder receive drugs than psychotherapy, mostly because they seek treatment from their primary care physician rather than a psychologist. One popular type of psychotherapy used to treat panic disorder is cognitive-behavioral therapy, or CBT (p. 559), which views the physiological arousal symptoms as a learned fear of certain bodily sensations and views the fear of being in closed or crowded situations as a behavioral response to expecting that the bodily sensations will intensify into a full-blown panic attack (Craske & Barlow, 2001). Given the various treatment options available for panic disorder, how do psychologists know for sure which treatment or combination of treatments is most effective?

Luisa received medication and psychotherapy.

3 Which Treatment Is Most Effective?

A comprehensive experiment including more than 300 people diagnosed with panic disorder used random assignment to place each participant in one of five treatment groups: drug only (a benzodiazepine), CBT only, placebo only, CBT plus drug, and CBT plus placebo (Craske & Barlow, 2001). The results showed that people who received drugs or CBT, as well as the combined treatments, showed more improvement than people in the placebo-only group. In regard to short-term treatment effects (measured after three months of treatment), CBT plus drugs was not better than CBT plus placebo, and people receiving combined treatments showed no more improvements than people receiving individual treatments. In regard to long-term treatment effects (six months after treatment had ended), many people in the drug-only group and CBT-plus-drug group relapsed. Thus, people treated with CBT alone or in combination with placebo did better than those who took medication. Though this study used only a benzodiazepine for drug treatment, similar research studies using an SSRI show comparable results. This suggests that CBT has a better long-term treatment benefit for panic disorder than medication.

4 Conclusions

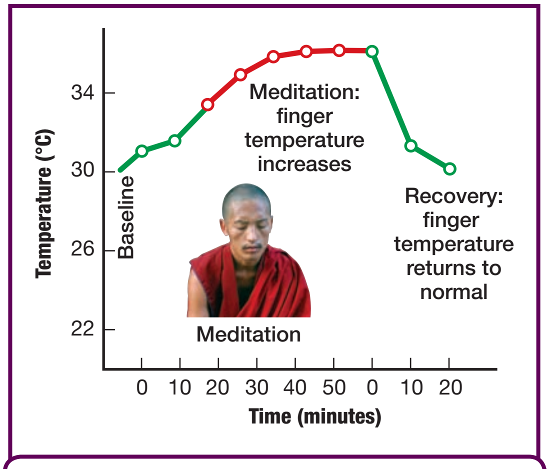
By using an experiment, researchers found that the use of CBT and drugs, either individually or combined, worked about equally well in the short term. However, the use of CBT without drugs led to the best long-term treatment effects. It is well established that over 80% of people with panic disorder who receive CBT will be panic-free at the end of treatment, and they generally continue to show long-term treatment benefits (Craske & Barlow, 2001). Therefore, treatment for panic disorder should include CBT.

Next, we'll look at how some monks develop mind-over-body control.

G. Cultural Diversity: Tibetan Monks

Monks' Amazing Abilities

Tibetan monks claim that by meditating they can voluntarily control their autonomic nervous systems to perform a number of responses, such as warming their hands (graph below). Since many Western researchers believe that voluntary control of the autonomic nervous system is very, very difficult to learn, Western researcher Herbert Benson and his colleagues from Harvard Medical School have traveled to India to scientifically test and verify the monks' amazing claims (H. Benson et al., 1982, 1990).



Tibetan monks use meditation to increase hand temperature, a response very difficult to control.

The *autonomic nervous system* has two divisions that are not usually under voluntary control: The sympathetic division causes physiological arousal by increasing heart rate, breathing, blood pressure, and secretion of hormones; the parasympathetic division calms and relaxes the body by decreasing physiological responses and stimulating digestion.

The only two responses of the autonomic nervous system that you can control ***voluntarily*** and ***without practice*** are breathing and eye blinking. All other responses of the autonomic nervous system, such as increasing or decreasing blood pressure, temperature, or heart rate and dilating or constricting blood vessels, are controlled automatically and, without considerable practice, are not under voluntary control.

If you want to voluntarily control one of your autonomic nervous system's responses, such as dilating blood vessels to warm your hands, sit quietly in a chair, close your eyes, and think relaxing thoughts. If you can think relaxing thoughts, they will activate your parasympathetic division, which will dilate blood vessels and result in warming your hands. However, the first time you try this, your hands will probably become colder because by trying so hard to relax, you may be doing the reverse: activating your sympathetic system, which causes arousal and constricts the blood vessels in your fingers.

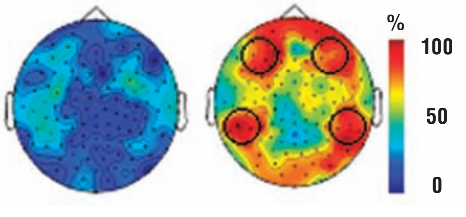
Westerners find it takes considerable practice to learn to warm our hands because we usually spend little time practicing how to produce relaxing thoughts. In comparison, certain Tibetan monks, through various forms of meditation, claim that they can warm their hands and bodies to such an extent that they can actually dry wet towels that are placed on their shoulders. This was exactly the kind of claim that excited and puzzled Benson's group of researchers.

Voluntary control—hand warming. Benson's group obtained permission from three monks at a monastery in India to measure their skin temperature during heat meditation, or g Tum-mo yoga. The monks sat in the lotus position, closed their eyes, and began meditating. As shown in the left graph, within a short period of time, one monk had raised his finger temperature as much as 7–9°C (or 9–12°F) with no change in heart rate (H. Benson et al., 1982). The monks' success at warming their hands was about five times as great as Westerners, who had managed only 0.25–2°F (Freedman, 1991). However, only a small number of monks can produce this kind of hand and body warming and only after 10 to 20 years of practice.

Explanation. Westerner Benson gave a very scientific explanation: Monks are able to raise their hand temperature by using thoughts to deeply relax, which in turn activates the parasympathetic division, which dilates tiny blood vessels that lie near the surface of the skin. The Tibetan monks' explanation is much more mysterious: During their meditation, the monks gather winds that are scattered in consciousness and focus these winds into a "central channel" that can generate a great internal body heat (H. Benson et al., 1982).

Studying the mind's abilities. The monks' ability to voluntarily control their physiological responses clearly shows the mind-body interaction as they use their thoughts to influence the difficult-to-control and normally involuntary autonomic nervous system. Recently, Western scientists completed a study in which a group of Buddhist monks extensively trained in meditation and a group of volunteers without meditation experience were instructed to meditate on unconditional compassion while brain wave activity was recorded. The results clearly showed that meditation activated the minds of the trained monks very differently from those of the volunteers. The Buddhist monks had greater activation of fast-moving and powerful ***gamma brain waves*** (40 cycles per second—much faster than REM brain waves; p. 153). It is interesting that the highest gamma brain wave activity was recorded in the left prefrontal cortex, which is associated with happiness and positive thoughts. These findings suggest Buddhist monks can rid themselves of negative emotions through gamma brain wave activity occurring during meditation (M. Kaufman, 2005; Talan, 2006a).

Although we are unlikely to ever achieve the monks' level of mind control, we'll next discuss several more easily learned techniques that can be used to reduce stress, decrease activation of the fight-flight response, and reduce the risk of developing psychosomatic symptoms.



As shown in these head diagrams, volunteers (above left) had low gamma brain wave activity and the Buddhist monks (above right) had high gamma brain wave activity during the meditation task.

H. Application: Stress Management Programs

Definition

How can I reduce my stress levels?

One reason 30% of college freshmen feel continuously overwhelmed is that their classes, exams, papers, personal problems, and part-time jobs combine to take more time and energy than they have (Duenwald, 2003). Being overwhelmed means increased levels of stress and increased risk of developing psychosomatic symptoms. One way to reduce levels of stress is with a stress management program.

A ***stress management program*** uses a variety of strategies to reduce anxiety, fear, and stressful experiences by changing three different aspects of our lives: thoughts (appraisals), behaviors, and physiological responses.

By controlling your thoughts you can control your body.

Psychologists have developed a number of very effective stress management programs that reduce stress levels, which in turn decrease the occurrence of psychosomatic symptoms. Although stress management programs have different names, they all focus on ways to change three major contributors to stressful experiences: your thoughts and beliefs (appraisals), your behaviors, and your emotional and physiological responses (Spiegler & Guevremont, 2009).

We'll describe several methods that psychologists have developed for effectively changing each of these three factors, beginning with changing your thoughts.

Changing Thoughts

Can you learn to think more positively?

Many daily hassles—dealing with long lines, slow traffic, rude people, loud neighbors, and sloppy roommates—can be made more or less stressful depending on how you appraise these situations. Since your appraisal of a situation as threatening or challenging is related to increasing or decreasing your stress levels, it follows that an effective way to decrease stressful experiences is to work at changing how you initially appraise a situation (Lazarus, 2000). We'll explain two effective strategies for changing your appraisals: thinking of potentially stressful situations as challenging rather than threatening and changing negative self-statements into positive ones.

Use Challenge Appraisals

The reason you want to think of or appraise potentially stressful situations as challenging rather than threatening is that threat appraisals elicit negative emotions (fear, anxiety, depression), which in turn raise stress levels, while challenge appraisals elicit positive emotions, which lower stress levels. For example, students who emphasize threat appraisals of exams, such as thinking they will not have time to study or expecting to do poorly, are more likely to experience negative emotions such as anxiety and fear (Shannon, 1994). In turn, anxiety and fear trigger the fight-flight response, which raises the level of stress and often leads to emotion-focused coping, such as complaining, seeking sympathy, or avoiding studying. However, emotion-focused coping does not usually motivate actions, such as studying, that are needed to prepare students for exams.

I see life as one big challenge!

In comparison, students who emphasize challenge appraisals of exams, such as wanting to do their best or to prove themselves, are more likely to experience positive emotions, such as excitement or eagerness, which decrease levels of stress. In turn, challenge appraisals are more likely to result in problem-focused coping, which means taking direct action to deal with the situation itself, such as developing a study program.

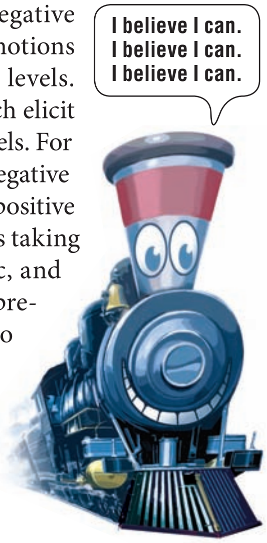
Thus, a good way to deal with potentially stressful situations is to focus on challenging rather than threatening appraisals (N. Skinner & Brewer, 2002).

Substitute Positive Self-Statements

Another way to prevent a situation, such as taking an exam, from becoming more stressful is to work at removing negative self-statements by substituting positive ones. Specifically, on one side of a sheet of paper write your negative self-statements; then next to them on the other side write the positive ones that you can substitute. The example below shows negative self-statements changed into positive ones.

Negative self-statements	Positive self-statements
"I know I'll do badly."	*"I know I can do OK."*
"I always get so anxious."	*"I'm going to stay calm."*
"I'm not smart enough."	*"I've got plenty of ability."*
"I'm never going to learn it."	*"I can learn the material."*

The reason you want to avoid making negative self-statements is that they elicit negative emotions (fear, anger, anxiety), which increase stress levels. By substituting positive self-statements, which elicit positive emotions, you can decrease stress levels. For example, each time you begin to think of a negative self-statement, stop yourself and substitute a positive one. For regularly occurring stressors, such as taking exams, waiting in lines, fighting with traffic, and dealing with rude people, it is best to have prepared a different list of self-statements to go with each different situation. Researchers found that a program of substituting positive self-statements proved very effective in helping people change their thought patterns and reduce their stress levels (Spiegler & Guevremont, 2009).



I believe I can.
I believe I can.
I believe I can.

Photo Credits: both, © PhotoDisc, Inc.

Changing Behaviors

How do you get ready for an exam?

There are generally two different ways that students get ready for exams. Some students get ready for an exam by complaining about how much work there is, making excuses about not studying, or blaming the instructor for too much material. These behaviors involve ***emotion-focused coping,*** which in the short term serves to reduce stress by decreasing negative emotional feelings. However, in the long run, students may need to change these behaviors and engage in ***problem-focused coping,*** which means developing a study plan (N. Skinner & Brewer, 2002).

Because some students are not aware of whether they use emotion-focused or problem-focused coping, stress management programs include an observation period of 1 to 2 weeks. During this time, a student observes or monitors his or her own behaviors to identify emotion-focused versus problem-focused behaviors. If a student is using primarily ***emotion-focused coping*** (making excuses, procrastinating, or blaming others), he or she will likely do poorly on exams. Instead, a student needs to start a program of ***problem-focused coping*** (making a study program, rewriting class notes) by using some of the self-reward and behavior modification techniques that we discussed in Module 10 (Spiegler & Guevremont, 2009). Thus, one way to reduce stress is to change your behaviors—that is, to emphasize problem-focused over emotion-focused activities.

I'd rather complain than change.

Learning to Relax

How do you learn to relax?

Learning to relax at will is important for developing a stress management program because being able to relax is one way to turn off the fight-flight response and decrease your body's heightened arousal. But unless you practice one of the following methods, you will find it very difficult to relax at will. In fact, when someone says "Just relax," you usually get tenser because you don't know how to relax. We'll describe three techniques that have proved almost equally effective at getting you to relax, and each involves using your mind (brain) to control your body's responses (S. L. Shapiro et al., 2000).

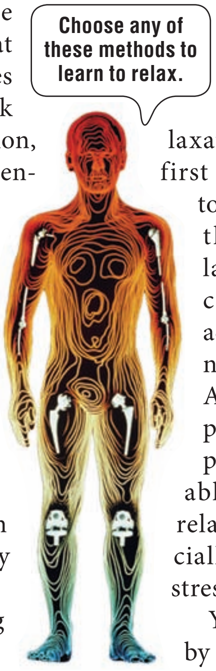
Biofeedback

You could learn a relaxing response, such as decreasing muscle tension, by having small sensors placed on your forehead. The sensors are attached to a machine that records, amplifies, and displays changes in muscle tension. Each time you think thoughts or images that increase tension, you hear a high tone; if you decrease tension, you hear a low tone. This procedure is called biofeedback (Spiegler & Guevremont, 2003).

Biofeedback **refers to voluntarily learning to control physiological responses, such as muscle activity, blood pressure, or temperature, by recording and displaying these responses.**

After 12 to 30 biofeedback training sessions (about 20 minutes per session), most individuals have some success in turning on relaxing responses, especially after being stressed.

You could also learn to relax by using progressive relaxation.



Choose any of these methods to learn to relax.

Progressive Relaxation

Progressive relaxation **involves practicing tensing and relaxing the major muscle groups of the body until you are able to relax any groups of muscles at will.**

With progressive relaxation, you usually begin by first tensing and relaxing your toes and then continuing up the body, tensing and relaxing the muscles of your calves, thighs, pelvis, stomach, shoulders, arms, hands, neck, face, and forehead. After several weeks of daily practice, about 20 minutes per session, you would be able to use this exercise to relax your body at will, especially immediately after being stressed.

You could also learn to relax by using a form of meditation.

Meditation

There are various kinds of meditation exercises. We'll describe two of the more popular ones, which are Eastern forms of meditation.

Transcendental meditation **(TM) and *yoga* involve assuming a comfortable position, closing your eyes, and repeating a sound or concentrating on your breathing so that you clear your head of all thoughts, worrisome and otherwise.**

Because meditation involves removing all worrisome or stressful thoughts and replacing them with peaceful ones, it can be an effective method for relaxing and reducing stress. Research on the benefits of meditation for stress management is so conclusive that many hospitals and medical clinics are teaching meditation to their patients. Meditation also provides some relief from anxiety and depression, and improved alertness, focus, and memory (Andrews, 2005; Lazar et al., 2005; Peng, 2008a).

However, learning to use meditation to relax at will usually requires practicing about 20 minutes a day for many weeks (J. Stein, 2003).

Stopping Stress Responses

The next time some stressor triggers the fight-flight response, you can use some form of relaxation to stop or turn down the heightened arousal caused by the fight-flight response and thus reduce your stressful or negative feelings before they result in psychosomatic symptoms, such as a headache or stomach distress. Researchers report that most relaxation techniques, whether biofeedback, progressive relaxation, or various forms of meditation (Zen, yoga, TM), are about equally effective in producing relaxation and reducing stress (S. L. Shapiro et al., 2000). For example, different relaxation techniques were about equally effective in reducing anxiety and decreasing a variety of psychosomatic complaints, such as headaches, high blood pressure, insomnia, stomach pain, and intestinal problems (irritable bowel syndrome) (Spiegler & Guevremont, 2009). More important than which relaxation technique you choose is daily practice so that you can learn to relax at will. Being able to relax at will is vital to developing an effective stress management program (J. Stein, 2003; M. Davis et al., 2008).

Summary Test

A. Appraisal

1. The uncomfortable feeling we have when we appraise a situation as something that overloads or strains our psychological resources is called __________.

2. Our initial, subjective evaluation of a situation in which we balance various environmental demands against our ability to meet them is called __________.

3. There are three outcomes of primary appraisal. Those situations that do not matter to our well-being are called (a) __________; those that will enhance or preserve our well-being are called (b) __________; and those that overtax our resources are called (c) __________.

4. A stressful situation has the potential for three different kinds of personal experiences. If you have already sustained some damage or injury, this is referred to as (a) __________. If the injury has not yet taken place but you anticipate it in the near future, this is referred to as (b) __________. If you have the potential for gain or personal growth but need to use physical energy and psychological resources, this is referred to as (c) __________. Not all appraisals are clear-cut; some may represent a combination of threat and challenge.

B. Physiological Responses

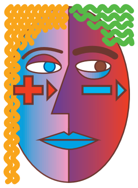
5. A combination of physiological responses that arouse and prepare the body for action is called the (a) __________ response. Although this response originally evolved to help our ancestors survive dangerous and life-threatening situations, it can also be triggered by psychological stimuli, such as our primary (b) __________ of a situation as harm/loss, threatening, or challenging.

6. Threat appraisals activate two brain areas, called the (a) __________ and __________, which trigger two responses simultaneously. The hypothalamus causes the (b) __________ gland to release ACTH, which acts on the adrenal cortex to secrete hormones that regulate levels of minerals and glucose in the body. It also triggers the (c) __________ division of the autonomic nervous system, which causes physiological arousal.

7. Our psychological reactions to stressful situations can result in real, painful, physical symptoms called (a) __________ symptoms. According to Selye, we develop psychosomatic symptoms because the body's response to stress involves going through three stages that he called the (b) __________ syndrome. The first is called the (c) __________ stage, which is our initial reaction to stress and is marked by physiological arousal. The second is called the (d) __________ stage, in which most physiological responses return to normal levels as the body uses up great stores of energy. The third is called the (e) __________ stage, which is marked by the actual breakdown in body organs or weakening of the infection-fighting immune system.

8. The body's network of cells and chemicals that automatically fight off bacteria, viruses, and other foreign matter is known as the (a) __________. The study of the relationships among the central nervous system, the endocrine system, and psychosocial factors is called (b) __________. The interaction among these factors affects the immune system and, in turn, makes the body more or less susceptible to disease and infection.

C. Stressful Experiences



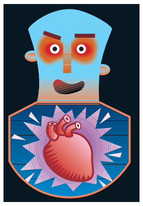
9. Situations that are potentially disturbing or disruptive and that we appraise as having an impact on our lives are called (a) __________ events. Small, irritating daily events are called (b) __________, and small, pleasant daily experiences are called (c) __________. How we cope with hassles predicts our daily mood and the occurrence of psychosomatic symptoms.

10. The feeling that results when our attempts to reach some goal are blocked is called (a) __________. Feelings of wearing out or becoming exhausted because of too many demands on our time and energy are referred to as (b) __________. A direct personal experience of actual or threatened death or serious injury or witnessing such an event could result in terrible stress symptoms called (c) __________.

11. When we must decide between two or more incompatible choices, we are in (a) __________, which can include at least three possibilities. If we must choose between two options with pleasurable consequences, we experience (b) __________ conflict. If we must choose between two options that both have disagreeable consequences, we are in (c) __________ conflict. If a single situation has both pleasurable and disagreeable aspects, we are in (d) __________ conflict.

12. An unpleasant state in which we have feelings of uneasiness and apprehension as well as increased physiological arousal is called (a) __________. This feeling has at least three causes. One is classical conditioning of an emotional response to a previously neutral stimulus; the result is called a (b) __________ response. A second cause is a form of learning that develops through watching and does not require any observable behavior or reinforcer; this is called (c) __________ learning. According to Freud, anxiety arises when the id and superego disagree, leading to an (d) __________ conflict, which results in the ego producing a feeling of anxiety.

D. Personality & Social Factors



13. Three personality traits that decrease the potentially harmful effects of stressful situations are control, commitment, and challenge, which together are called ______________.

14. If you believe that what you do influences what happens, you are said to have an (a) ______________ of control. In contrast, if you believe that chance and luck mostly determine what happens and that you do not have much influence, you are said to have an (b) ______________ of control. People with an external locus of control experience more negative emotions, higher levels of stress, and more psychosomatic symptoms than do those whose locus of control is internal.

15. Currently, the major components of Type A behavior are (a) ______________ and ______________. Individuals with these traits are many times more likely to have a (b) ______________. Also, individuals who always show or always suppress anger and hostility have greater increases in (c) ______________, which can have damaging effects one's heart and health.

16. One factor that buffers us from stressful experiences is having a group or network of family or friends who provide strong support; this is called ______________.

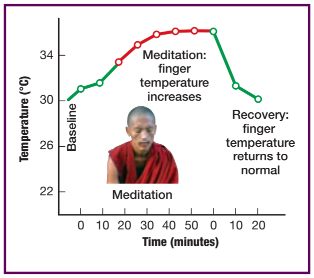
E. Kinds of Coping

17. After we make a primary appraisal, we then must decide what action to take, which is called a (a) ______________ appraisal. This involves two different kinds of coping. If we seek information about what needs to be done, change our own behavior, or take whatever action will solve the problem, we use (b) ______________ coping. If we use our energies to deal with emotional distress caused by a harm or threat appraisal, we are using (c) ______________ coping. Compared to emotion-focused coping, problem-focused coping is better at reducing long-term effects of stress because it solves the problem.

F. Research Focus: Treatment for Panic Disorder

18. Psychologists use a number of different research methods. One method is an in-depth analysis of the thoughts, feelings, beliefs, or behaviors of individuals; this is called the (a) ______________. Another method identifies cause-and-effect relationships by following a set of guidelines that describe how to control and manipulate variables; this is called the (b) ______________ method. Panic disorder is usually treated with (c) ______________. By using an experiment, researchers found the use of cognitive-behavioral therapy and drugs, either individually or combined, worked equally well in terms of (d) ______________ treatment effects. Research findings showed that the most effective long-term treatment for panic disorder is (e) ______________.

G. Cultural Diversity: Tibetan Monks



19. Many of our physiological responses involved in relaxation (heart rate, blood pressure, temperature, and secretion of hormones) are not under voluntary control because they are regulated by the (a) ______________ system. Researchers discovered that some monks have learned a method to voluntarily control temperature, which involves relaxation. This demonstrates that the (b) ______________ can be used to control the (c) ______________ physiological responses.

H. Application: Stress Management Programs

20. A program for reducing anxiety, fear, and stressful experiences by using a variety of strategies to change three different aspects of our lives—thoughts, behaviors, and physiological responses—is called a ______________.

21. One component of a stress management program is learning to relax at will, which can be accomplished with three different methods. Recording and amplifying physiological signals from the body and displaying these signals so that we can learn to increase or decrease them is known as (a) ______________. An exercise of tensing and relaxing the major muscle groups is called (b) ______________. Meditation can take many forms. Sitting or lying in a comfortable position while repeating a meaningless sound over and over to rid oneself of anxious thoughts is called (c) ______________. Researchers have found that all three techniques are about equally effective in helping us to relax.

Answers: *1. stress; 2. primary appraisal; 3. (a) irrelevant, (b) positive, (c) stressful; 4. (a) harm/loss, (b) threat, (c) challenge; 5. (a) fight-flight, (b) appraisal; 6. (a) amygdala, hypothalamus, (b) pituitary, (c) sympathetic; 7. (a) psychosomatic, (b) general adaptation, (c) alarm, (d) resistance, (e) exhaustion; 8. (a) immune system, (b) psychoneuroimmunology; 9. (a) major life, (b) hassles, (c) uplifts; 10. (a) frustration, (b) burnout, (c) posttraumatic stress disorder; 11. (a) conflict, (b) approach-approach, (c) avoidance-avoidance, (d) approach-avoidance; 12. (a) anxiety, (b) conditioned emotional, (c) observational, (d) unconscious; 13. hardiness; 14. (a) internal locus, (b) external locus; 15. (a) hostility, anger, (b) heart attack, premature heart disease, (c) physiological arousal; 16. social support; 17. (a) secondary, (b) problem-focused, (c) emotion-focused; 18. (a) case study, (b) experimental or scientific, (c) drugs and/or psychotherapy, (d) short-term, (e) cognitive-behavioral therapy; 19. (a) autonomic nervous or parasympathetic, (b) mind, (c) body's; 20. stress management program; 21. (a) biofeedback, (b) progressive relaxation, (c) transcendental meditation (TM)*

Critical Thinking

Coping with Cancer

At age 25, world-renowned cyclist Lance Armstrong was training rigorously and cycling better than ever. His training schedule resulted in his legs, feet, back, neck, and just about every other body part being in pain. So, he didn't pay much attention when he noticed his right testicle was slightly swollen. Soon, he began to feel much more tired than usual. Then he began having vision trouble, and one morning he coughed up blood. He could no longer pretend something wasn't wrong.

Doctors diagnosed Lance with testicular cancer that had spread to his abdomen, lungs, and brain. When he first heard his doctor say "You have cancer," his fear became very real. Lance had third-degree testicular cancer (the most serious kind), and he was given less than a 40% chance of surviving. He would have surgery to remove his right testicle and brain lesions, followed by months of chemotherapy.

After leaving the doctor's office, Lance shared his diagnosis with family and friends. He received an overwhelming amount of support as his friends and family routinely called and visited. Lance also began learning as much as he could about cancer, what it is and how it is treated. He even began seeking second, third, and fourth medical opinions. Learning more about cancer provided him with some reassurance and comfort.

Lance felt so anxious about his diagnosis and treatment that he blocked out memory of what he thought and felt the morning of his risky brain surgery. In the midst of chemotherapy, he kept cycling, wanting to believe that if he could continue to cycle, then somehow he wouldn't be sick. Eventually, Lance became so weak from chemotherapy he could barely walk. Then, instead of feeling hopeless, he chose to believe in his doctors and in his treatment. He began to envision himself overcoming cancer.

Today, Lance Armstrong is a cancer survivor. He now seizes each day as an opportunity to enjoy his life. Since his recovery, he won the Tour de France, the 2,290-mile road race that's considered the single most grueling sporting event in the world, a record seven consecutive times! When asked about his trying experience with cancer, he said, "The truth is that cancer was the best thing that ever happened to me. I don't know why I got the illness, but it did wonders for me, and I wouldn't want to walk away from it. Why would I want to change, even for a day, the most important and shaping event in my life?" (Armstrong, 2001, p. 4).

Lance is now trying to make a change in the lives of others. He accomplishes this not only by being a role model to people all over the world, but also by being a passionate advocate for better cancer research and treatment to improve the experiences of people who have cancer. Lance is definitely a fighter while on his bicycle, and he's no different when it comes to doing everything he can to help find the cure for cancer. (Adapted from Armstrong, 2001, 2007; Hutchinson, 2009)

QUESTIONS

1 After Lance noticed his right testicle was swollen, which Freudian defense mechanism does he use to deal with this potentially damaging news, and what is his primary appraisal of the situation?

2 Which kinds of personality traits help Lance cope with the stress of knowing that he has cancer?

3 Why is it good news that his family and friends kept calling and visiting?

4 Which type of coping is Lance using by educating himself about cancer?

5 Which Freudian defense mechanism(s) is Lance using during treatment?

6 How does Lance cope with cancer both near the end of his treatment and now that he has survived cancer?

Learning Activities

PowerStudy for Introduction to Psychology 4.5

PowerStudy 4.5™

Try out **PowerStudy's SuperModule** for Health, Stress & Coping! In addition to the quizzes, learning activities, interactive Summary Test, key terms, module outline and abstract, and extended list of correlated websites provided for all modules, the DVD's **SuperModule** for Health, Stress & Coping features:

- Self-paced, fully narrated learning with a multitude of animations.
- Videos about topics including support groups for women with breast cancer, links between stress and your immune system, and links between emotion and physical health.
- Interactive versions of study resources, including the Summary Test on pages 504–505 and the critical thinking questions for the article on page 506.

Visit this book's companion website for more resources to help you study, including learning objectives, additional quizzes, flash cards, updated links to useful websites, and a pronunciation glossary.

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. Lance initially dismissed the problem, which is using the Freudian defense mechanism of denial to cope with the problem. However, after he had vision problems and coughed up blood, his primary appraisal changed to one of threat (Will the swollen testicle be cancerous?), which increased his level of stress.
2. Lance will be better able to cope with the news of having testicular cancer if he has the personality traits of hardiness (control, commitment, challenge), if he has an internal rather than an external locus of control, and if he has a more optimistic than pessimistic attitude toward life.
3. Lance is using emotion-focused coping to deal with his fear and anxiety by seeking support from his family and friends. Social support is a powerful way to reduce levels of stress as well as help prepare and be a buffer for future stressful situations.
4. Problem-focused coping is a long-term strategy to deal with the stressful problem itself—in this case, learning more about cancer and his treatment options.
5. By blocking out memory of what he thought and felt before undergoing brain surgery, Lance was using the Freudian defense mechanism of repression to cope with his problem. He was using the Freudian defense mechanism of rationalization by convincing himself that by continuing to cycle, he would not have cancer.
6. Lance began to have an optimistic attitude about having cancer and his chances of overcoming it. Being optimistic can help lower stress levels and improve mood.

Introduction

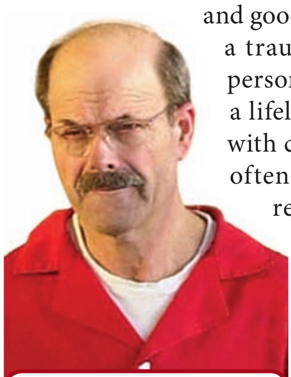
Mental Disorder

How did a serial killer go unnoticed?

He was a loving husband, devoted father, respected church elder, and straitlaced county official. He also worked for a home security company, where he would help individuals protect themselves from dangerous people. Until the day he was caught, he blended into the Wichita community as an average next-door neighbor. But over a period of 17 years, Dennis Rader planned and carried out the cruel murders of 10 people. He became known as the "BTK killer," which stands for Bind, Torture, and Kill, describing the methods he used with his victims.

In a very real sense, Rader led two different lives. In public, Rader seemed like a quiet, law-abiding guy who helped to protect the safety of others. However, in private, Rader would break into people's homes, hide, and then sneak up on his victims. He would proceed to tie them up, callously strangle them, and eventually murder them.

Although no two serial killers are alike, Rader fits the typical pattern. Serial killers usually look like ordinary people, often with families and good jobs. Many serial killers have experienced a traumatic childhood event and have serious personality defects, such as low self-esteem and a lifelong sense of loneliness. They are obsessed with control, manipulation, and dominance and often con their victims into agreeing to their requests. Most serial killers enjoy not the actual killing, but the ruthless torturing of their victims. This explains why serial killers feel special when their victims suffer and plead for help, and why Rader became sexually aroused as he strangled each of his victims (Hickey, 2006; Mann, 2005).



Dennis Rader, who murdered 10 people, fits the pattern of serial killers.

When Rader's trial began, his defense attorneys had to decide whether they wanted to claim he was legally insane when he committed the murders. You are probably thinking that a person who coldheartedly plans and carries out 10 violent murders must certainly be insane, but let's consider what it means to be insane.

Insanity, **according to its legal definition, means not knowing the difference between right and wrong.**

As inhumane as Rader's behaviors may seem, his defense did not claim he was insane. Based on Rader's testimony, it was clear he knew all along that his actions were wrong and conducted for his own selfish interests. In 2005, thirty-one years after the first BTK attacks, Rader was charged with 10 counts of first-degree murder for which he must serve 10 life sentences (Davey, 2005; O'Driscoll, 2005; Wilgoren, 2005).

When mental health professionals examine Rader's behaviors, they are trying to identify his particular mental disorder.

A *mental disorder* is generally defined as a prolonged or recurring problem that seriously interferes with an individual's ability to live a satisfying personal life and function adequately in society.

Deciding whether a person has a mental disorder can be difficult because so many factors are involved in defining what is abnormal. As you'll learn in this module, someone's behavior may be described as abnormal but the person may or may not have a mental disorder.

Phobia

What's so scary about flying?

There is no doubt that Dennis Rader's murder and mutilation of 10 individuals indicate extremely abnormal behavior and a severe mental disorder (Hickey, 2006). In other cases, mental disorders may involve a relatively common behavior or event that, through some learning, observation, or other process, has the power to elicit tremendous anxiety and becomes a phobia (Rowa et al., 2006).

A *phobia (FOE-bee-ah)* is an anxiety disorder characterized by an intense, excessive, and irrational fear that is out of all proportion to the danger elicited by the object or situation.

Kate Premo's phobia of flying began in her childhood, when she experienced a turbulent flight that left her scared and anxious. Later, as a young adult, her fear of flying was worsened by memories of the 1988 terrorist bombing of Pan Am flight 103, which killed several of her fellow students from Syracuse University. After that incident, her phobia of flying kept her from visiting friends and family. She would try to fly and even make reservations but always cancel them at the last minute.

Kate Premo is trying to overcome her phobia of flying.

An estimated 9% of American adults have a similar irrational and intense fear of flying, which is called ***aviophobia;*** they refuse to get on a plane. Another 27% of American adults report being at least somewhat afraid to fly (*USA Today*/CNN/Gallup, 2006). To treat her phobia, Kate Premo (photo above) took part in a weekend seminar that included actually flying in a plane. We'll tell you about Kate's phobia and treatment later in this module.

These two examples of Dennis Rader and Kate Premo raise a number of questions about mental disorders: How do they develop? How are they diagnosed? How are they treated? We'll answer these three questions as we discuss mental disorders.

What's Coming

In this module, we'll discuss three approaches to understanding mental disorders. We'll explain how mental disorders are assessed and diagnosed and go into some specific examples of mental disorders, such as generalized anxiety, phobias, obsessive-compulsive behaviors, and somatoform disorders. Finally, we'll discuss how common phobias, such as fear of flying, are treated.

We'll begin with the different factors that are involved in defining, explaining, and treating mental disorders, such as that of Dennis Rader.

A. Factors in Mental Disorders

Causes of Abnormal Behavior

Explanations for the causes of mental disorders have changed dramatically through the centuries. In the Middle Ages, mental disorders were thought to be the result of demons or devils who inhabited individuals and made them do strange and horrible things. In the 1600s, mental disorders were thought to involve witches, who were believed to speak to the devil. This was the case in Salem, Massachusetts, in 1692, where, in a short span of four months, 14 women and 5 men were hanged as witches on the testimony of young girls and God-fearing adults (L. Shapiro, 1992). In the 1960s, one major cause of mental disorders was thought to be environmental factors, such as stressful events. In the 1990s came advances in studying genetic factors as well as new methods to study the structures and functions of living brains (p. 70). As a result, current researchers and clinicians believe that mental disorders, such as that of Dennis Rader, result from a number of factors, which include biological, cognitive-emotional-behavioral, and environmental influences (Hersen & Thomas, 2006).

Biological Factors

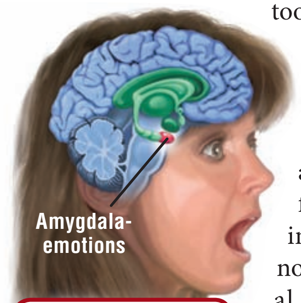
Biological influences include genetic or inherited factors and various neurological factors that influence how the brain functions.

Genetic factors. As an infant, Joan would cry, show great fear, and try to avoid new or novel objects or situations. Because Joan showed great fear as an infant, researchers concluded that her fearfulness was primarily due to genetic factors (Kagan, 2003a).

Genetic factors **that contribute to the development of mental disorders are unlearned or inherited tendencies that influence how a person thinks, behaves, and feels.**

Genetic factors operate by affecting the developing brain and/or the neurotransmitters that the brain uses for communication. Researchers estimate that genetic factors contribute from 30% to 60% to the development of mental disorders, such as depression, schizophrenia, and anxiety disorders (Rutter & Silberg, 2002).

Neurological factors. Joan, who had started life as a fearful infant, had developed a serious mental disorder called a social phobia (p. 518) by the time she was 20. Researchers believed that one reason she developed a social phobia was that her brain's emotional detector, called the amygdala (p. 362), was overactive and too often identified stimuli as threatening when they were only new or novel. In fact, when researchers measured the activity (fMRI) of Joan's amygdala, they found that her amygdala overreacted when she looked at new or novel faces, something that did not happen in the amygdalas of individuals who did not have social phobias (C. E. Schwartz et al., 2003). In a related study, individuals who had developed social phobias, like Joan, showed far more amygdala activity when looking at angry, fearful, or disgusted faces than did individuals without social phobias (Luan et al., 2006). The studies illustrate neurological factors, such as having an overactive brain structure that contributes to the development of a mental disorder by causing a person to see the world in a biased or distorted way and to see threats when none really exist.



Very fearful adults had more activity in the amygdala.

Although these studies show that biological factors—genetic and neurological—can contribute to the development of mental disorders, not everyone with an overactive amygdala develops a mental disorder. This means that other factors are also involved in the development of mental disorders.

Cognitive-Emotional-Behavioral & Environmental Factors

Because biological factors themselves do not always explain why people develop mental disorders, psychologists point to various cognitive-emotional-behavioral factors that interact with and contribute to developing mental disorders.

Cognitive-emotional-behavioral and environmental factors **that contribute to the development of mental disorders include deficits in cognitive processes, such as having unusual thoughts and beliefs; deficits in processing emotional stimuli, such as under- or overreacting to emotional situations; behavioral problems, such as lacking social skills; and environmental challenges, such as dealing with stressful situations.**

Unusual thoughts, emotions, behaviors, or events contribute to developing mental disorders.

For example, Dennis Rader was a shy and polite child who preferred to spend time alone. As a boy, he recalls watching his grandparents strangle chickens at their farm, and by the time he reached high school, he was strangling cats and dogs. Rader's hobby during childhood was looking at pictures of women in bondage. By his teens, he fantasized about tying up, controlling, and torturing women. He was becoming increasingly bothered by murderous impulses but did not know how to tell anyone about it (Ortiz, 2005; Singular, 2006). Rader's many maladaptive thoughts, emotions, and behaviors interacted with his biological factors and resulted in his serious mental disorder.

Environmental factors. In some cases, traumatic events, such as being in a war, having a serious car accident, watching some horrible event (a dog attacking and killing a child), or being brutally mugged, assaulted, or raped, can result in a long-lasting emotional disorder called posttraumatic stress disorder, or PTSD. As we discussed earlier (p. 491), a person with PTSD may relive the terrible event through memories and nightmares and have serious emotional problems that often require professional help (Resick et al., 2008). Experiencing PTSD is an example of how traumatic environmental factors can contribute to developing a serious mental disorder.

Many factors. The answer to why Joan developed a social phobia, or Dennis Rader became a serial killer, or a family member, friend, or relative developed a mental disorder involves a number of factors—genetic, neurological, cognitive-emotional-behavioral, and environmental. As several or more of these factors interact, the result in some cases can be the development of one of the mental disorders that we'll discuss in this and the next module.

Definitions of Abnormal Behavior

Is Mr. Thompson abnormal?

In some cases, such as Dennis Rader's murder and mutilation of 10 individuals, we have no doubt that he demonstrated an extremely abnormal behavior pattern. In other cases, such as Kate Premo's phobia of flying, we would probably say that most of her life appears to be normal except for a small piece—fear of flying in airplanes—that is abnormal. In still other cases, such as that of 54-year-old Richard Thompson (right photo), it is less clear what is abnormal behavior.

The City of San Diego evicted Thompson and all his belongings from his home. His belongings included shirts, pants, dozens of shoes, several Bibles, a cooler, a tool chest, lawn chairs, a barbecue grill, tin plates, bird cages, two pet rats, and his self-fashioned bed. For the previous nine months, Thompson had lived happily and without any problems in a downtown storm drain (sewer). Because the city does not allow people to live in storm drains, however, Thompson was evicted from his underground storm-drain home and forbidden to return. Although Thompson later lived in several care centers and mental hospitals, he much preferred the privacy and comfort of the sewer (Grimaldi, 1986).

There are three different ways to decide whether Richard Thompson's behavior—living in the sewer—was abnormal.

Is it abnormal to live in a storm drain if you don't bother anyone?

Statistical Frequency

Although Thompson caused no problems to others except to violate a city law against living in a storm drain, his preferred living style could be considered abnormal according to statistical frequency.

The *statistical frequency approach* says that a behavior may be considered abnormal if it occurs rarely or infrequently in relation to the behaviors of the general population.

By this definition, Thompson's living in a storm drain would be considered very abnormal since, out of over 300 million people in the United States, only a very few prefer his kind of home. This illustrates that even though statistical frequency is a relatively precise measure, it is not a very useful measure of abnormality. By this criterion, getting a Ph.D., being president, living in a monastery, and selling a million records are abnormal, although some of these behaviors would be considered very desirable by most people. In fact, Guinness World Records (2009) lists thousands of people who have performed some statistically abnormal behaviors and are very proud of them. We would not consider any of these individuals to necessarily have mental disorders.

According to statistical frequency, living in a monastery is abnormal.

As all these examples demonstrate, the statistical frequency definition of abnormality has very limited usefulness.

Deviation from Social Norms

Thompson's behavior—preferring to live in a sewer—could also be considered abnormal based on social norms.

The *social norms approach* says that a behavior is considered abnormal if it deviates greatly from accepted social standards, values, or norms.

Thompson's decision to live by himself in a storm drain greatly deviates from society's norms about where people should live. However, a definition of abnormality based solely on deviations from social norms runs into problems when social norms change with time. For example, 25 years ago, very few males wore earrings, while today many males consider earrings very fashionable. Similarly, 40 years ago, a woman who preferred to be very thin was considered to be ill and in need of medical help. Today, our society pressures women to be thin like the fashion models in the media.

According to social norms, living in a storm drain is abnormal.

Thus, defining abnormality on the basis of social norms can be risky, as social norms may, and do, change over time. The definition of abnormality most used by mental health professionals is the next one.

Maladaptive Behavior

The major problem with the first two definitions of abnormal behavior—statistical frequency and deviation from social norms—is that they don't say whether a particular behavior is psychologically damaging or maladaptive.

The *maladaptive behavior approach* defines a behavior as psychologically damaging or abnormal if it interferes with the individual's ability to function in his or her personal life or in society.

For example, being terrified of flying, hearing voices that dictate dangerous acts, feeling compelled to wash one's hands for hours on end, starving oneself to the point of death (anorexia nervosa), and Dennis Rader's committing serial murders would all be considered maladaptive and, in that sense, abnormal.

However, Thompson's seemingly successful adaptation to living in a sewer may not be maladaptive for him and certainly has no adverse consequences to society.

Most useful. Of the three definitions discussed here, mental health professionals find that the most useful definition of abnormal behaviors is the one based on the maladaptive definition—that is, whether a behavior or behavior pattern interferes with a person's ability to function normally in society (Sue et al., 2010).

According to the maladaptive definition, behavior is abnormal if it interferes with a person's functioning.

However, you'll see that deciding whether behavior is truly maladaptive is not always so easy.

B. Assessing Mental Disorders

Definition of Assessment

How do you find out what's wrong?

In some cases, it's relatively easy to identify what's wrong with a person. For example, it's clear that Dennis Rader was a serial killer and that Kate Premo has an intense and irrational fear of flying. But in other cases, it's more difficult to identify exactly what the person's motivation and mental problem are. Take the tragic case of Susan Smith.

Susan first said her sons were kidnapped but later confessed that she had drowned them.

Susan Smith appeared on the "Today" show, crying for the return of her two little boys (right photo), Michael, 3 years old, and Alex, 14 months old, who, she said, had been kidnapped. She begged the kidnapper to feed them, care for them, and please, please, return them. And then, nine days later, after a rigorous investigation turned up doubts about the kidnapping story, the police questioned Susan again. Not only did she change her story, but she made the teary confession that she had killed her two children. She said that she had parked her car by the edge of the lake, strapped her two children into their car seats, shut the windows and doors, got out of the car, walked to the rear, and pushed the car into the lake. She covered her ears so she couldn't hear the splash. The car disappeared under the water. The two little boys, strapped into their seats, drowned.

Susan's confession stunned the nation as everyone asked, "How could she have killed her own children?" "What's wrong with Susan?" To answer these questions, mental health professionals evaluated Susan's mental health with a procedure called the clinical assessment (J. M. Wood et al., 2002).

A ***clinical assessment*** involves a systematic evaluation of an individual's various psychological, biological, and social factors, as well as identifying past and present problems, stressors, and other cognitive or behavioral symptoms.

A clinical assessment is the first step in figuring out which past or current problems may have contributed to Susan killing her own children (Begley, 1998b). We'll discuss how a clinical assessment is done.

Three Methods of Assessment

How was Susan evaluated?

After Susan's arrest, mental health professionals did clinical assessments to try to discover what terrible forces pushed her over the edge. Depending on their training, mental health professionals use one or more of three major techniques—neurological exams, clinical interviews, and psychological tests—to do clinical assessments.

Neurological Tests

We can assume that Susan was given a number of ***neurological tests*** to check for possible brain damage or malfunction. These tests might include evaluating reflexes, brain structures (MRI scans), and brain functions (fMRI scans—p. 70).

Neurological exams are part of a clinical assessment because a variety of abnormal psychological symptoms may be caused by tumors, diseases, or infections of the brain.

Did Susan have neurological problems?

Neurological tests are used to distinguish physical or organic causes (tumors) from psychological ones (strange beliefs) (Zillmer et al., 2008). Susan was reported to have no neurological problems.

Clinical Interviews

As part of her clinical assessment, several psychiatrists spent many hours interviewing Susan. This method is called a clinical interview (Hersen & Thomas, 2007).

The ***clinical interview*** is one method of gathering information about a person's past and current behaviors, beliefs, attitudes, emotions, and problems. Some clinical interviews are unstructured, which means they have no set questions; others are structured, which means they follow a standard format of asking a similar set of questions.

During the clinical interview, Susan would have been asked about the history of her current problems, such as when they started and what other events accompanied them. The focus of the interview would have been on Susan's current problem, killing her children, especially on the details of the symptoms that led up to the killing. The clinical interview is perhaps the primary technique used to assess abnormal behavior (Durand & Barlow, 2006).

What are Susan's past and current psychological problems?

Based on 15 hours of interviews, Dr. Seymour Halleck testified that Susan was scarred by her father's suicide and her stepfather sexually abusing her, which led to periods of depression, her current problem (Towle, 1995).

Psychological Tests

As part of her assessment, psychologists may have given Susan a number of personality tests (pp. 450, 474).

Personality tests include two different kinds of tests: objective tests (self-report questionnaires), such as the MMPI, which consist of specific statements or questions to which the person responds with specific answers, and projective tests, such as the Rorschach inkblot test, which have no set answers but consist of ambiguous stimuli that a person interprets or makes up a story about.

As we also discussed in Modules 19 and 20, personality tests help clinicians evaluate a person's traits, attitudes, emotions, and beliefs.

Purpose. A major goal of doing a clinical assessment is to decide which mental health disorder best accounts for a client's symptoms. For example, based on her symptoms, Susan was described as having a mood disorder, which you'll see next is one of many possible mental health problems.

C. Diagnosing Mental Disorders

Real-Life Assessment

What can a clinical assessment tell us?

In criminal trials that involve questions of mental health, the defense and prosecution usually hire their own psychiatrists or psychologists because they are looking for different problems or symptoms. In Susan's case, at least two psychiatrists did clinical assessments to answer a number of questions: What are her current symptoms? What past events and situations caused these symptoms? What role did her symptoms play in the killing of her children?

Her Past

During clinical interviews, the psychiatrist found that when Susan was 8 years old, her father shot himself. When she was 13, psychologists wanted to admit her to a hospital to treat her depression, but her mother and stepfather refused to cooperate. Later, when Susan was 15, her stepfather sexually molested her, but her mother refused to press charges. When she was in high school, she had periods of depression and attempted suicide. However, she did well academically, was an honor student and a member of the math club, and was voted the "friendliest female" in the class of 1989. She married David in 1991, but one year after the birth of their second son, their marriage fell apart and they filed for divorce (Bragg, 1995).

Dr. Seymour Halleck testified that Susan was scarred by her father's suicide, her stepfather's sexual abuse, and her periods of depression, which contributed to her current difficulties (Towle, 1995).

Susan's clinical assessment revealed a disturbed person. She is being led away to serve a life sentence.

Her Present

The psychiatrist found that Susan's present problems included becoming depressed after being rejected by her current boyfriend. She confessed to being so lonely in the months before the killings that she had multiple sexual encounters: with her stepfather, who had molested her as a teenager; with her estranged husband, whom she was divorcing; with her current boyfriend, who later wrote a good-bye letter; and with her boyfriend's father. In addition, Susan was drinking heavily during this period.

Dr. Halleck testified that Susan suffered from severe depression, drinking, and an adjustment disorder that caused her to have a heightened emotional reaction to stress (D. Morgan, 1995).

In just 2½ hours, the jury decided that Susan Smith was guilty of murder. She was led from the courthouse (upper left photo) to serve a life sentence.

As a result of her clinical assessment, Susan was diagnosed as having a mood disorder and was treated in prison with antidepressants.

A clinical assessment is a method of identifying a client's symptoms, which are used to make a diagnosis. Making a diagnosis requires matching the symptoms to a particular disorder, which involves using the DSM-IV-TR.

DSM-IV-TR

How many mental disorders?

Those who knew Susan tried to diagnose the problem that led to her tragic crime.

"Maybe Susan was just plain crazy." "Maybe she was too depressed to know what she was doing." "Maybe she had bad genes." "Maybe something bad happened to her as a child."

Using a more rigorous method, mental health professionals conduct clinical assessments to identify symptoms, which are then used to make a clinical diagnosis.

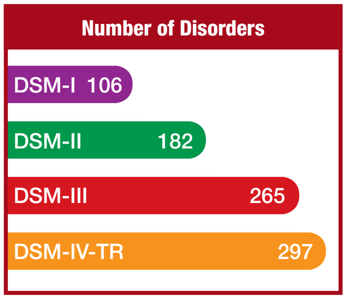
A ***clinical diagnosis*** is a process of matching an individual's specific symptoms to those that define a particular mental disorder.

Making a clinical diagnosis was very difficult prior to the 1950s because there was no uniform code or diagnostic system. However, since 1952, the American Psychiatric Association (APA) has been developing a uniform diagnostic system, whose most recent version is known as the *Diagnostic and Statistical Manual of Mental Disorders*-IV-Text Revision, abbreviated as DSM-IV-TR (American Psychiatric Association, 2000).

The ***Diagnostic and Statistical Manual of Mental Disorders***-IV-Text Revision, or DSM-IV-TR, describes a uniform system for assessing specific symptoms and matching them to almost 300 different mental disorders.

With each revision of the DSM, there have been improvements in diagnosing mental disorders. For example, the DSM-II (1968) gave only general descriptions of mental problems because it was based on Sigmund Freud's general concepts of ***psychoses*** (severe mental disorders, such as schizophrenia) and ***neuroses*** (less severe forms of psychological conflict, such as anxiety). Using only general descriptions caused disagreements in diagnosing problems. The DSM-III (1980) dropped Freudian terminology and instead listed specific symptoms and criteria for mental disorders. However, these criteria were based primarily on clinical opinions, not research, so disagreements continued. A major improvement in the current DSM-IV-TR is that it establishes criteria and symptoms for mental disorders based more on research findings than on clinical opinions (L. A. Clark et al., 1995). When the next DSM comes out, likely in 2012, mental health experts predict that it will use new findings from genetics and neuroscience to better identify the underlying causes of mental disorders (First, 2007; M. C. Miller, 2007).

Interestingly, the first *Diagnostic and Statistical Manual of Mental Disorders* (1952) described about 100 mental disorders, as compared to almost 300 in the most recent DSM-IV-TR (right figure).



We'll use the cases of Dennis Rader (serial killer), Susan Smith (murderer), and Kate Premo (phobia of flying) to show how mental health professionals use the DSM-IV-TR to make a diagnosis.

C. Diagnosing Mental Disorders

Nine Major Problems: Axis I

How do we make a diagnosis?

In making a clinical diagnosis, a mental health professional first assesses the client's specific symptoms and then matches these symptoms to those described in the DSM-IV-TR. The DSM-IV-TR has five major dimensions, called axes, which serve as guidelines for making decisions about symptoms. We'll first describe Axis I and show how it can be used to diagnose the very different problems of Susan Smith and Kate Premo. (The numbered items below and on the opposite page are based on the *Diagnostic and Statistical Manual of Mental Disorders-IV-Text Revision* [2000], American Psychiatric Association.)

Axis I: Nine Major Clinical Syndromes

Axis I contains lists of symptoms and criteria about the onset, severity, and duration of these symptoms. In turn these lists of symptoms are used to make a clinical diagnosis of the following nine major clinical syndromes.

1. Disorders usually first diagnosed in infancy, childhood, or adolescence.

This category includes disorders that arise before adolescence, such as attention-deficit disorders, autism, mental retardation, enuresis, and stuttering (discussed in Modules 1, 2, and 13).

2. Organic mental disorders.

These disorders are temporary or permanent dysfunctions of brain tissue caused by diseases or chemicals, such as delirium, dementia (Alzheimer's—p. 50), and amnesia (p. 265).

3. Substance-related disorders.

This category refers to the maladaptive use of drugs and alcohol. Mere consumption and recreational use of such substances are not disorders. This category requires an abnormal pattern of use, as with alcohol abuse and cocaine dependence (pp. 188–189).

4. Schizophrenia and other psychotic disorders.

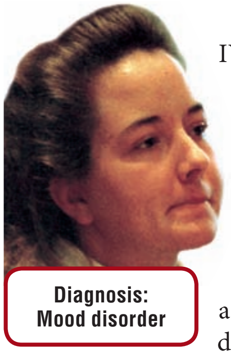
The schizophrenias are characterized by psychotic symptoms (for example, grossly disorganized behavior, delusions, and hallucinations) and by over six months of behavioral deterioration. This category, which also includes delusional disorder and schizoaffective disorder, will be discussed in Module 23.

5. Mood disorders.

The cardinal feature is emotional disturbance. Patients may or may not have psychotic symptoms. These disorders, including major depression, bipolar disorder, dysthymic disorder, and cyclothymic disorder, are discussed in Module 23. Susan Smith is an example of a person with a mood disorder.

Susan Smith: Diagnosis—Mood Disorder

From childhood on, Susan's symptoms include being depressed, attempting suicide, seeking sexual alliances to escape loneliness, drinking heavily, and having feelings of low self-esteem and hopelessness, all of which match the DSM-IV-TR's list of symptoms for a mood disorder. In Susan's case, the specific mood disorder most closely matches major depressive disorder but without serious thought disorders and delusions.



Diagnosis: Mood disorder

In diagnosing major depression, the DSM-IV-TR distinguishes between early (before age 21) and late onset depression—Susan would be early, and between mild and severe depression, as judged by how many episodes of depression she had and whether she showed a decreased capacity to function normally, such as the inability to work or care for children. Susan's ability to hold a job and care for her children suggests mild depression. This example shows how the guidelines of Axis I are used to arrive at one of nine major clinical syndromes—in this case, major depression.

6. Anxiety disorders.

These disorders are characterized by physiological signs of anxiety (for example, palpitations) and subjective feelings of tension, apprehension, or fear. Anxiety may be acute and focused (phobias) or continual and diffuse (generalized anxiety disorder). An example of an anxiety disorder is that of Kate Premo.

Kate Premo: Diagnosis—Specific Phobia

Diagnosis: Specific phobia (aviophobia)

Kate Premo's symptoms include having an intense fear of flying, knowing that her fear is irrational and that she can't control it, going out of her way to avoid flying, and making reservations that she later cancels. Kate's symptoms most closely match the DSM-IV-TR's list of symptoms for an anxiety disorder called a specific phobia. The DSM-IV-TR's symptoms for a specific phobia match those of Premo—experiencing intense and irrational fear when exposed to a feared situation (flying) and having to avoid that situation at all costs, which interferes with part of her normal activities (going to meetings).

7. Somatoform disorders.

These disorders are dominated by somatic symptoms that resemble physical illnesses. These symptoms cannot be accounted for by organic damage. There must also be strong evidence that these symptoms are produced by psychological factors or conflicts. This category, which includes somatization and conversion disorders and hypochondriasis, will be discussed in this module.

8. Dissociative disorders.

These disorders all feature a sudden, temporary alteration or dysfunction of memory, consciousness, identity, and behavior, as in dissociative amnesia and multiple personality disorder (discussed in Module 23).

9. Sexual and gender-identity disorders.

There are three types of disorders in this category: gender-identity disorders (discomfort with identity as male or female), paraphilias (preference for unusual acts to achieve sexual arousal), and sexual dysfunctions (impairments in sexual functioning) (discussed in Module 15).

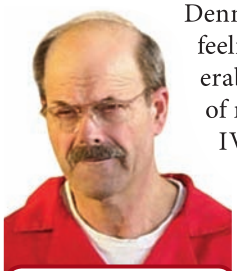
Other Problems and Disorders: Axes II, III, IV, V

We have explained how Axis I is used to make clinical diagnoses of such mental disorders as major depression (mood disorder) and specific phobias (fear of flying). Now, we'll briefly describe how the other four axes are used in diagnosing problems.

Axis II: Personality Disorders

This axis refers to disorders that involve patterns of personality traits that are long-standing, maladaptive, and inflexible and involve impaired functioning or subjective distress. Examples include borderline, schizoid, and antisocial personality disorders. Personality disorders will be discussed in Module 23. An example of a personality disorder is that of Rader.

Dennis Rader: Diagnosis—Antisocial Personality Disorder



Diagnosis: Antisocial personality disorder

Dennis Rader's symptoms include torturing and killing 10 individuals, feeling no guilt or remorse, and exhibiting this behavior over a considerable period of time. Rader's symptoms may indicate a combination of mental disorders, but here we'll focus on only one from the DSM-IV-TR, a personality disorder. According to the DSM-IV-TR, the essential features of an antisocial personality disorder are strange inner experiences that differ greatly from the expectations of one's culture, that lead to significant impairment in personal, occupational, or social functioning, and that form a pattern of disregard for, and violation of, the rights of others. This list of symptoms from the DSM-IV-TR matches those of Rader.

Axis III: Personality Disorders

This axis refers to physical disorders or conditions, such as diabetes, arthritis, and hemophilia, that have an influence on someone's mental disorder.

Axis IV: Psychosocial and Environmental Problems

This axis refers to psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis of mental disorders in Axes I and II. A psychosocial or environmental problem may be a negative life event (experiencing a traumatic event), an environmental difficulty or deficiency, a familial or other interpersonal stress, an inadequacy of social support or personal resources, or another problem that describes the context in which a person's difficulties have developed (PTSD was discussed on p. 491).

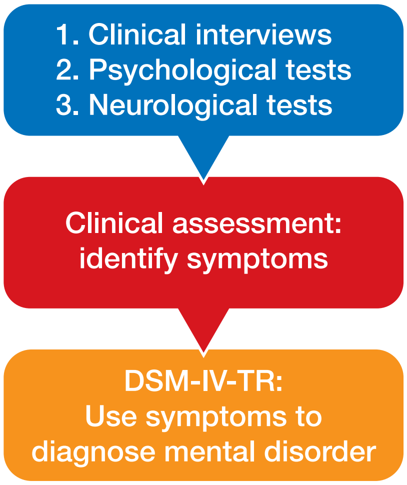
Axis V: Global Assessment of Functioning Scale

This axis is used to rate the overall psychological, social, and occupational functioning of the individual on a scale from 1 (severe danger of hurting self) to 100 (superior functioning in all activities).

Using all five axes. Mental health professionals use all five axes to make a clinical diagnosis. For example, in the case of Dennis Rader, his unusual sexual symptoms may match those of a sexual disorder in ***Axis I.*** His other maladaptive symptoms match those of an antisocial personality disorder in ***Axis II.*** Rader apparently had no related medical conditions listed in ***Axis III.*** Rader was a loner with poor self-esteem and struggled with his schoolwork, which match some of the psychological, social, and environmental factors listed in ***Axis IV.*** Amazingly, Rader functioned well enough to hold a job and go unnoticed in his neighborhood, which would be used to rate his general functioning listed in ***Axis V.*** As you can see, each of the five axes in the DSM-IV-TR focuses on a different factor that contributes to making an overall clinical diagnosis of a person's mental health.

Usefulness of DSM-IV-TR

The figure below shows the steps in making a clinical diagnosis. Mental health professionals begin by using three different methods to identify a client's symptoms, a process called clinical assessment. Next, the client's symptoms are matched to the five axes in the DSM-IV-TR to arrive at a diagnosis of each client's particular mental disorder.



1. Clinical interviews
2. Psychological tests
3. Neurological tests
Clinical assessment: identify symptoms
DSM-IV-TR: Use symptoms to diagnose mental disorder

For mental health professionals, there are three advantages of using the DSM-IV-TR's uniform system to diagnose and classify mental disorders (Widiger & Clark, 2000).

First, mental health professionals use the classification system to communicate with one another and discuss their clients' problems.

Second, researchers use the classification system to study and explain mental disorders.

Third, therapists use the classification system to design their treatment program so as to best fit a particular client's problem.

Although using the DSM-IV-TR system to diagnose mental problems has advantages, it also has a number of potential problems. For example, mental health professionals do not always agree on whether a client fits a particular diagnosis. In addition, there may be social, political, and labeling problems, which we'll discuss next.

C. Diagnosing Mental Disorders

Potential Problems with Using the DSM-IV-TR

Is labeling a problem?

It's not uncommon to hear people use labels, such as "Jim's really anxious," "Mary Ann is compulsive," or "Vicki is schizophrenic." Although the goal of the DSM-IV-TR is to give mental disorders particular diagnostic labels, once a person is labeled, the label itself may generate a negative stereotype. In turn, the negative stereotype results in negative social and political effects, such as biasing how others perceive and respond to the labeled person (Greatley, 2004).

Labeling Mental Disorders

David Oaks, a sophomore at Harvard University, was having such fearful emotional experiences that he was examined by a psychiatrist. Although David believed that he was having a mystical experience, the psychiatrist interpreted and labeled David's fearful experiences as indicating a kind of short-term schizophrenic disorder (Japenga, 1994). This mental health professional made a clinical diagnosis that resulted in giving a label to David's problem.

Some labels (anxious, depressed) have negative stereotypes.

Labeling **refers to identifying and naming differences among individuals. The label, which places individuals into specific categories, may have either positive or negative associations.**

At first David felt relieved to know that his problem had a diagnosis or label. Later he realized that his new label was changing his life for the worse. People no longer responded to him as David-the-college-sophomore but as David-with-schizophrenic-disorder.

As David's case shows, the ***advantage*** of diagnostic labels is their ability to summarize and communicate a whole lot of information in a single word or phrase. But, the ***disadvantage*** is that if the label has negative associations—for example, mentally ill, retarded, schizo—the very label may elicit negative or undesirable responses. For this reason, mental health professionals advise that we not respond to people with mental disorders by their labels and instead respond to the person behind the label (Albee & Joffe, 2004).

Social and Political Implications

Diagnostic labels can change how a person is perceived and thus have political and social implications. For instance, in the 1970s, gays protested that homosexuality should not be included in the DSM-I and II as a mental disorder. When studies found that homosexuals were no more or less mentally healthy than heterosexuals, homosexuality as a mental disorder was eliminated from the DSM-III.

In the 1980s, women protested the DSM label of self-defeating personality disorder because the label applied primarily to women who were said to make destructive life choices, such as staying in abusive relationships (Japenga, 1994). This label was dropped from the DSM-IV because it suggested that women were choosing bad relationships, which wasn't true (P. Caplan, 1994).

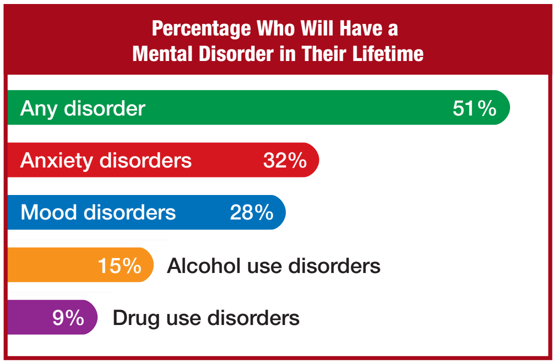
Despite these advances, labeling continues to be a serious problem. For instance, 68% of Americans don't want someone with a mental illness marrying into their family and 58% don't want people with mental illness at their workplace (J. K. Martin et al., 2000). Also, even though mental illness does not increase the chance of someone being violent, many Americans still believe that people with mental illness tend to behave in violent ways (Elbogen & Johnson, 2009).

Japan has a special problem with labels: Mental disorder labels have very negative connotations, which discourages Japanese from seeking professional help for mental disorders. One result is that, compared to the United States, Japan has a very high rate of suicide. That's because one risk for suicide is depression, a label the Japanese avoid and thus they do not get timely treatment. In comparison, in the United States, the label of depression is widely accepted, so people are more likely to be treated, even by doctors in general practice (Menchetti et al., 2009).

These examples illustrate the social and political implications of labeling individuals with mental disorders.

Frequency of Mental Disorders

Although labels are a fact of life, researchers and clinicians try to apply the DSM labels as fairly as possible. Researchers interviewed a national sample of 9,282 noninstitutionalized civilians aged 18 and older and diagnosed their problems using the DSM's diagnostic system. As the graph at the right shows, based on those surveyed, 51% of people will develop at least one disorder during their lifetime (Kessler et al., 2005). The most common mental disorder was anxiety, followed by mood disorders and substance abuse, especially problems with alcohol.



Percentage Who Will Have a Mental Disorder in Their Lifetime

What was surprising was that 59% of those with a mental disorder had neither asked for nor received any professional treatment. This study also found that about 50% of all lifetime mental disorders begin by age 14 and 75% begin by age 24.

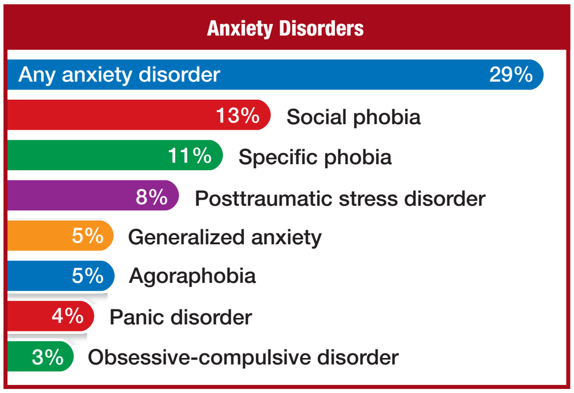
Researchers concluded that about one in two people will develop a mental disorder sometime in their life, most individuals with a mental disorder do not seek treatment, and there is a need to understand how to best treat mental disorders in youth.

Next, we'll examine the symptoms and treatment of specific disorders, beginning with anxiety.

D. Anxiety Disorders

How common is anxiety?

The most common mental disorder reported by adults in the United States is any kind of anxiety disorder (right graph) (Kessler et al., 2005). We have already discussed two serious anxiety problems, panic disorder (p. 481) and posttraumatic stress disorder (PTSD) (p. 491). Here we'll review panic disorder and PTSD, as well as discuss other common forms of anxiety: generalized anxiety disorder, three kinds of phobias, and obsessive-compulsive disorder.

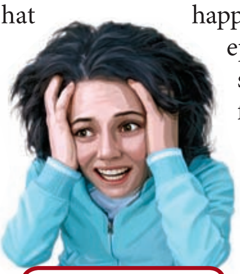


Generalized Anxiety Disorder

During his initial therapy interview, Fred was sweating, fidgeting in his chair, and repeatedly asking for water to quench a never-ending thirst. From all indications, Fred was visibly distressed and extremely nervous. At first, Fred spoke only of his dizziness and problems with sleeping. However, it soon became clear that he had nearly always felt tense. He admitted to a long history of difficulties in interacting with others, difficulties that led to his being fired from two jobs. He constantly worried about all kinds of possible disasters that might happen to him (Davison & Neale, 1990). Fred's symptoms showed that he was suffering from generalized anxiety disorder.

Generalized anxiety disorder (GAD) is characterized by excessive or unrealistic worry about almost everything or feeling that something bad is about to happen. These anxious feelings occur on a majority of days for a period of at least six months (American Psychiatric Association, 2000).

About 5% of adults are reported to have GAD, but almost twice as many adult women (6.6%) report GAD as do men (3.6%) (Halbreich, 2003).



Anxiety can be treated with drugs and psychotherapy.

Symptoms

Generalized anxiety disorder includes both psychological and physical symptoms. Psychological symptoms include being irritable, having difficulty concentrating, and being unable to control one's worry, which is out of proportion to the actual event. Constant worrying causes significant distress or impaired functioning in social, occupational, and other areas. Physical symptoms include restlessness, fatigue, sweating, flushing, pounding heart, insomnia, headaches, and muscle tension or aches (American Psychiatric Association, 2000).

Treatment

Generalized anxiety disorder is commonly treated with psychotherapy (see Module 24), with or without drugs. The drugs most frequently prescribed are tranquilizers such as alprazolam and diazepam, which belong to a group known as the ***benzodiazepines*** *(ben-zoh-die-AS-ah-peens)*. One of the limitations of these drugs is that at high doses they are addicting and interfere with the ability to remember newly learned information (Arkowitz & Lilienfeld, 2007a; Rupprecht et al., 2009). Antidepressant drugs are also used to treat GAD and have fewer side effects and a lower risk of addiction (Holmes & Newman, 2006).

Researchers found that about 40–50% of clients treated for generalized anxiety disorder with either psychotherapy (cognitive-behavioral) or drugs (tranquilizers) were free of symptoms six months to one year later (Arntz, 2003; Holmes & Newman, 2006).

Panic Disorder

One afternoon, Luisa (pictured below), a 23-year-old college student, was walking on campus and she suddenly felt her heart rate rapidly accelerate, her throat tighten up, and her arms and legs tremble. She became so nauseous she almost vomited. Luisa felt she had no control over what was happening. Then, weeks later, while at the movies, she had another episode during which she experienced dizziness, chest pain, shortness of breath, and weakness in her legs and feet. She feared she was having a heart attack and might die, but after a series of tests, her doctors found no medical problem. Luisa's symptoms indicate that she had a panic disorder.

Panic disorder is characterized by recurrent and unexpected panic attacks (described below). The person becomes so worried about having another panic attack that this intense worrying interferes with normal psychological functioning (American Psychiatric Association, 2000).

Like Luisa, about 4% of adults in the United States suffer from panic disorder, and women are two to three times more likely to report it than are men (Halbreich, 2003). People who suffer from panic disorder have an increased risk of alcohol and other drug abuse, an increased incidence of suicide, decreased social functioning, and less marital happiness. About half suffer from depression (Smits et al., 2006).

Symptoms

Luisa's symptoms on campus and at the movies indicate that she was having a panic attack, which may occur in several different anxiety disorders but is the essential feature of panic disorder.

A ***panic attack*** is a period of intense fear or discomfort in which four or more of the following symptoms are present: pounding heart, sweating, trembling, shortness of breath, feelings of choking, chest pain, nausea, feeling dizzy, and fear of losing control or dying (American Psychiatric Association, 2000).

Treatment

Panic disorders are usually treated with drugs—benzodiazepines, antidepressants (Prozac-like drugs, which are selective serotonin reuptake inhibitors, or SSRIs)—and/or psychotherapy. Research indicates psychotherapy is at least as effective as drug therapy and drug therapy alone increases the risk of clients relapsing after treatment ends (Smits et al., 2006). Researchers found that, one year after treatment with a combination of psychotherapy and drugs, about 30–50% of clients were symptom-free (Page, 2002).

Another kind of anxiety disorder that is relatively common involves different kinds of phobias.

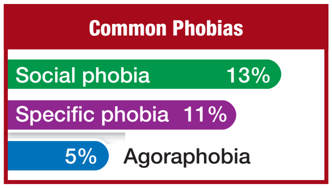
D. Anxiety Disorders

Phobias

Can fear go wild?

When common fears of seeing blood, spiders, or mice, having injections, meeting new people, speaking in public, flying, or being in small places turn into very intense fears, they are called phobias (over 500 phobias are listed on www.phobialist.com).

A ***phobia*** (FOE-bee-ah) is an anxiety disorder characterized by an intense and irrational fear that is out of all proportion to the possible danger of the object or situation. Because of this intense fear, which is accompanied by increased physiological arousal, a person goes to great lengths to avoid the feared event. If the feared event cannot be avoided, the person feels intense anxiety.

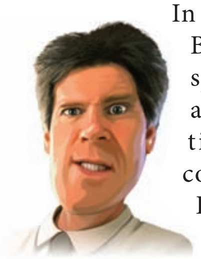


Reseachers report that because many individuals with phobias trace their onset to specific traumatic events, phobias are learned through conditioning or observing a person showing fear of something. Research also points to genetic and environmental causes of phobias. Thus, different pathways may lead to people developing phobias (Rowa et al., 2006).

We discussed fear of blood and injections earlier (pp. 201, 493). Here we'll discuss three common phobias—social phobias, specific phobias, and agoraphobia (graph at left) (Durand & Barlow, 2006).

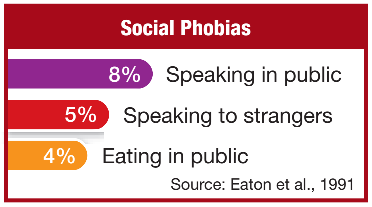
Social Phobias

Why didn't Billy speak up in class?



In junior high school, Billy never, never spoke up in class or answered any questions. The school counselor said that Billy would be sick to his stomach the whole day if he knew that he was going to be called on. Billy began to hide out in the restrooms to avoid going to class. Billy's fear of speaking up in class is an example of a social phobia (Durand & Barlow, 2010).

Social phobias are characterized by irrational, marked, and continuous fear of performing in social situations. The individuals fear that they will humiliate or embarrass themselves (American Psychiatric Association, 2000).



Source: Eaton et al., 1991

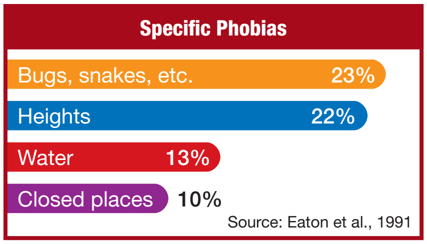
As a fearful social situation approaches (graph above), anxiety builds up and may result in considerable bodily distress, such as nausea, sweating, and other signs of heightened physiological arousal. Although a person with a social phobia realizes that the fear is excessive or irrational, he or she may not know how to deal with it, other than by avoiding the situation.

Specific Phobias

Why couldn't Kate get on a plane?

In the beginning of this module, we told you about Kate Premo (photo at left), whose traumatic childhood and adult experiences with flying turned into a phobia of flying, which is called a specific phobia.

Specific phobias, formerly called simple phobias, are characterized by marked and persistent fears that are unreasonable and triggered by anticipation of, or exposure to, a specific object or situation (flying, heights, spiders, seeing blood) (American Psychiatric Association, 2000).



Source: Eaton et al., 1991

Among the more common specific phobias seen in clinical practice (graph above) are fear of animals (zoophobia), fear of heights (acrophobia), fear of confinement (claustrophobia), fear of injury or blood, and fear of flying (Durand & Barlow, 2006).

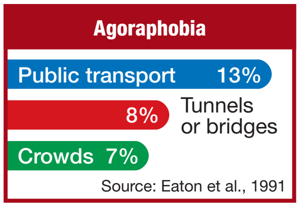
The content and occurrence of specific phobias vary with culture. For example, fears of spirits or ghosts are present in many cultures but become specific phobias only if the fear turns excessive and irrational (American Psychiatric Association, 2000).

Agoraphobia

Why couldn't Rose leave her house?

Fear trapped Rose in her house for years. If she thought about going outside to do her shopping, pain raced through her arms and chest. She grew hot and perspired. Her heart beat rapidly and her legs felt like rubber. She said that thinking about leaving her house caused stark terror, sometimes lasting for days. This 39-year-old mother of two is one of millions of Americans suffering from an intense fear of being in public places, which is called agoraphobia (*Los Angeles Times,* October 19, 1980).

Agoraphobia is characterized by anxiety about being in places or situations from which escape might be difficult or embarrassing (graph above) if a panic attack or paniclike symptoms (sudden dizziness or onset of diarrhea) were to occur (American Psychiatric Association, 2000).



Source: Eaton et al., 1991

Agoraphobia arises out of an underlying fear of either having a full-blown panic attack or having a sudden and unexpected onset of paniclike symptoms.

After any of these phobias are established, they are extremely persistent and may continue for years if not treated (M. E. Coles & Horng, 2006). We'll discuss drug and psychological treatments for phobias later in this module—in the Application section.

Next, we'll look at another form of anxiety that can be very difficult to deal with—obsessive-compulsive disorder.

Obsessive-Compulsive Disorder

Why was Shirley always late?

Shirley was an outgoing, popular high-school student with average grades. Her one problem was that she was late for school almost every day. Before she could leave the house in the morning, she had to be sure she was clean, so she needed to take a shower that lasted a full 2 hours. After her shower, she spent a long time dressing because, for each thing she did, such as putting on her stockings, underclothes, skirt, and blouse, she had to repeat the act precisely 17 times. When asked about her washing and counting, she said she knew it was crazy but she just had to do it and couldn't explain why (Rapoport, 1988). Shirley's symptoms would be diagnosed as indicative of an anxiety problem called obsessive-compulsive disorder.

An ***obsessive-compulsive disorder*** consists of obsessions, which are persistent, recurring irrational thoughts, impulses, or images that a person is unable to control and that interfere with normal functioning, and compulsions, which are irresistible impulses to perform over and over some senseless behavior or ritual (hand washing, checking things, counting, putting things in order) (American Psychiatric Association, 2000).

WASH
WASH
WASH
WASH
WASH
WASH
WASH

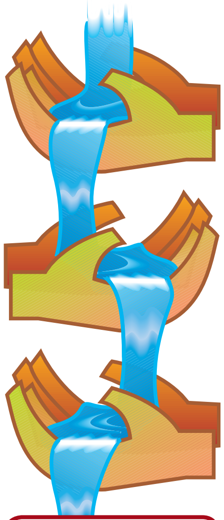
Repeating an act 17 times is a sign of OCD.

Obsessive-compulsive disorder, or OCD, was once considered relatively rare, but now it is known to affect about 3% of adults in the United States (Riggs & Foa, 2006). We'll discuss OCD's symptoms and treatments.

Symptoms

Shirley's symptoms included both obsession—need to be very clean and careful about dressing—and compulsions—need to take 2-hour showers and to perform each act of dressing precisely 17 times. Some individuals have obsessions (irrational, recurring thoughts) without compulsions. Because compulsions are usually very time-consuming, they often take an hour or more to complete each day.

Common compulsions involve cleaning, checking, and counting; the less common include buying, hoarding, and putting things in order. For example, individuals obsessed with being contaminated reduce their anxiety by washing their hands until their skin is raw, while those obsessed with leaving a door unlocked may be driven to check the lock every few minutes (American Psychiatric Association, 2000). These kinds of obsessive-compulsive behaviors interfere with normal functioning and make holding a job or engaging in social interactions difficult. OCD can be a chronic problem that requires treatment with drugs, psychotherapy, or some combination (Riggs & Foa, 2006).



Treatment for OCD is psychotherapy and/or antidepressant drugs.

Treatment

Shirley's compulsive behaviors are thought to be one way that she reduces or avoids anxiety. Currently, about half of patients with OCD report improvement after being treated with drugs or exposure therapy (Franklin et al., 2002).

Exposure therapy involves gradually exposing the person to the actual anxiety-producing situations or objects that he or she is attempting to avoid and continuing the exposure treatments until the anxiety decreases.

For example, a client like Shirley with OCD could be exposed over and over to her fearful objects (dirt or dirty things) until such exposures elicit little or no anxiety. Exposure therapy may involve 15 two-hour sessions over the course of a month. However, Shirley refused to try exposure therapy and instead was given antidepressant drugs.

Clients like Shirley, who cannot tolerate or are not motivated to undergo exposure therapy, may be given antidepressant drugs. After taking an antidepressant for about three weeks, Shirley's urges to wash and count faded sufficiently that she could try exposure therapy (Rapoport, 1988). However, about one-third of clients with OCD are not helped by antidepressants (Riggs & Foa, 2006).

A new, last resort treatment for OCD is deep brain stimulation (p. 61) (DeNoon, 2009b; Talan, 2009).

Next, we'll describe how a threatening event can lead to posttraumatic stress disorder.

Photo Credit: right, © Chip Simons/Science Faction/Corbis

Posttraumatic Stress Disorder

Mark was driving home from work when a huge truck unexpectedly lost control and rammed his car from behind. Mark had no way to escape the traumatic accident. Though he needed hospital treatment, he was lucky to walk away alive. However, since the accident Mark has become so fearful of driving that he works from home now. He still experiences troublesome, recurring memories of the event and frequently has terrifying nightmares about being in a car accident. Mark's symptoms would be diagnosed as indicative of an anxiety problem called posttraumatic stress disorder.

Posttraumatic stress disorder, or PTSD, is a disabling condition that results from personally experiencing an event that involves actual or threatened death or serious injury or from witnessing or hearing of such an event happening to a family member or close friend. People suffering from PTSD experience a number of psychological symptoms, including recurring and disturbing memories, terrible nightmares, and intense fear and anxiety (APA, 2000).

These horrible memories and feelings of fear keep stress levels high and result in a range of psychosomatic symptoms, including sleep problems, pounding heart, and stomach problems (Marshall et al., 2006; Schnurr et al., 2002).

Treatment. Treatment may involve drugs, but some form of cognitive-behavioral therapy (p. 568) is more effective in the long term (Bolton et al., 2004). Cognitive-behavioral therapy provides emotional support so victims can begin the healing process, helps to slowly eliminate the horrible memories by bringing out the details of the experience, and gradually replaces the feeling of fear with a sense of courage (Harvey et al., 2003; Resick et al., 2008).

Next, we'll discuss how people can create real physical symptoms that interfere with normal functioning.

E. Somatoform Disorders

Definition and Examples

Imagine someone whose whole life centers around physical symptoms, some that are imagined and others that appear real, such as developing paralysis in one's legs. This intense focus on imagined, painful, or uncomfortable physical symptoms is characteristic of individuals with somatoform disorders.

Somatoform** (so-MA-tuh-form) **disorders are marked by a pattern of recurring, multiple, and significant bodily (somatic) symptoms that extend over several years. The bodily symptoms (pain, vomiting, paralysis, blindness) are not under voluntary control, have no known physical causes, and are believed to be caused by psychological factors (American Psychiatric Association, 2000).

Although not easily diagnosed, somatoform disorders are among the most common health problems seen in general medical practice (Wise & Birket-Smith, 2002). The DSM-IV-TR lists seven kinds of somatoform disorders. We'll discuss two of the more common forms—somatization and conversion disorders.

A psychologically distressed individual may have painful physical symptoms that have no physical causes.

Somatization Disorder

One kind of somatoform disorder, which was historically called hysteria, is now called somatization disorder and is relatively rare (2.7% of the population).

Somatization disorder begins before age 30, lasts several years, and is characterized by multiple symptoms—including pain, gastrointestinal, sexual, and neurological symptoms—that have no physical causes but are triggered by psychological problems or distress (American Psychiatric Association, 2000).

This disorder is especially common among women (P. Fink et al., 2004). Those who have somatization disorder use health services frequently and have twice the annual medical care costs of people without somatization disorder (Barsky et al., 2005). Many people with somatization disorder are raised in emotionally cold and unsupportive family environments and are often victims of emotional or physical abuse (R. J. Brown et al., 2005). Somatization disorders may be a means of coping with a stressful situation or obtaining attention (Durand & Barlow, 2010).

Conversion Disorder

Some people report serious physical problems, such as blindness, that have no physical causes and are examples of conversion disorder, a type of somatoform disorder.

A ***conversion disorder*** refers to changing anxiety or emotional distress into real physical, motor, sensory, or neurological symptoms (headaches, nausea, dizziness, loss of sensation, paralysis) for which no physical or organic cause can be identified (American Psychiatric Association, 2000).

Usually the symptoms of a conversion disorder are associated with psychological factors, such as depression, concerns about health, or the occurrence of a stressful situation. Recent research examining the brains of people with medically unexplainable paralysis has shown that when patients try to move their paralyzed limbs, the emotional areas of the brain are activated inappropriately and may inhibit the functioning of the motor cortex, leaving the patients unable to move their paralyzed limbs (Kinetz, 2006). The development of such physical symptoms gets the person attention, removes the person from threatening or anxiety-producing situations, and thus reinforces the occurrence and maintenance of the symptoms involved in the conversion disorder (Durand & Barlow, 2010). Researchers found that in some cultures, bodily complaints (somatoform disorders) are used instead of emotional complaints to express psychological problems (Lewis-Fernandez et al., 2005).

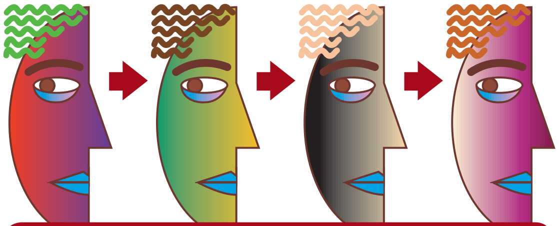
The same kind of painful or uncomfortable physical symptoms observed in somatoform disorders are observed in individuals suffering from mass hysteria.

Mass Hysteria

As more than 500 students from various schools began to give a choir and orchestra concert, they suddenly began to complain of headaches, dizziness, weakness, abdominal pain, and nausea. These symptoms spread rapidly until about half the students developed one or more of the symptoms. Students who became ill were most often those who saw someone near them become ill. Students from one school, particularly girls in the soprano section, experienced the highest rate of symptoms. Younger members reported more symptoms than older ones, and girls (51%) reported more symptoms than boys (41%). At first, someone thought that a gas line had broken, but no one in the audience developed any symptoms. There was no ruptured gas line. The students' symptoms resulted from mass hysteria (Small et al., 1991).

Mass hysteria is a condition experienced by a group of people who, through suggestion, observation, or other psychological processes, develop similar fears, delusions, abnormal behaviors, or physical symptoms.

In this case, several of the most popular and visible girls complained of feeling dizzy and nauseous (they had been standing for hours). Soon, other students were complaining about having similar physical symptoms until over 200 students eventually developed these same symptoms. A similar case of mass hysteria was reported in a group of teenage girls in Vietnam, 50 of whom were hospitalized due to sudden fainting after watching one girl collapse and be carried away by medical personnel (IANS, 2006).



Individuals who are emotionally aroused in a group may experience similar physical symptoms.

In the Middle Ages, hysteria was attributed to possession by evil spirits or the devil. Today, mass hysteria is known to involve members of a group who experience and share emotional arousal or excitement, which spreads through the group and results in its members developing ***real physical symptoms*** with no known physical causes (Barlow & Durand, 2009). Mass hysteria is another example of somatoform disorders.

After the Concept Review, we'll discuss how symptoms of mental disorders can vary among cultures, as we examine a disorder that seems to be unique to Asian cultures, especially Japan.

Photo Credit: left, © Marvin Mattelson

Concept Review

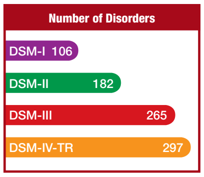
1. A prolonged or recurring problem that seriously interferes with the ability of an individual to live a satisfying personal life and function in society is called a ______________.

2. Mental disorders arise from the interaction of a number of factors. Biological factors include inherited behavioral tendencies, which are called (a) ______________ factors. These factors contribute from 30% to 60% to the development of mental disorders. Biological factors also include the overreaction of brain structures to certain stimuli, which are called (b) ______________ factors. Other factors that contribute to the development of mental disorders, such as deficits or problems in thinking, processing emotional stimuli, and social skills, are called (c) ______________ factors. Being in or seeing a traumatic event, which is called an (d) ______________ factor, can contribute to developing a mental disorder such as PTSD.

3. There are three definitions of abnormality. A behavior that occurs infrequently in the general population is abnormal according to the (a) ______________ definition. A behavior that deviates greatly from accepted social norms is abnormal according to the (b) ______________ definition. Behavior that interferes with the individual's ability to function as a person or in society is abnormal according to the (c) ______________ definition, which is used by most mental health professionals.

4. When performed by a mental health professional, a systematic evaluation of an individual's various psychological, biological, and social factors that may be contributing to his or her problem is called a clinical (a) ______________. A mental health professional who determines whether an individual's specific problem meets or matches the standard symptoms that define a particular mental disorder is doing a clinical (b) ______________. One of the primary techniques used to gather an enormous amount of information about a person's past behavior, attitudes, and emotions and details of current problems is the clinical (c) ______________.

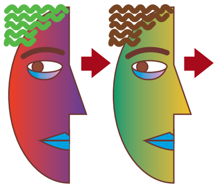
5. The manual that describes the symptoms for almost 300 different mental disorders is called the (a) ______________. The manual's primary goal is to provide mental health professionals with a means of (b) ______________ mental disorders and (c) ______________ that information in a systematic and uniform way. The DSM-IV-TR has five major dimensions, called (d) ______________, that serve as guidelines for making decisions about symptoms.



6. There are several kinds of anxiety disorders. An anxiety disorder that is characterized by excessive and/or unrealistic worry or feelings of general apprehension about events or activities, when those feelings occur on a majority of days for a period of at least six months, is called (a) ______________ disorder. An anxiety disorder marked by the presence of recurrent and unexpected panic attacks, plus continued worry about having another panic attack, when such worry interferes with psychological functioning, is called a (b) ______________ disorder. Suppose a person has a period of intense fear or discomfort during which four or more of the following symptoms are present: pounding heart, sweating, trembling, shortness of breath, feelings of choking, chest pain, nausea, feeling dizzy, and fear of losing control or dying. That person is experiencing a (c) ______________.

7. An anxiety disorder characterized by an intense and irrational fear and heightened physiological arousal that is out of all proportion to the danger elicited by the object or situation is called a (a) ______________, of which there are several kinds. Unreasonable, marked, and persistent fears that are triggered by anticipation of, or exposure to, a specific object or situation are called a (b) ______________. An anxiety that comes from being in places or situations from which escape might be difficult or embarrassing if a panic attack or paniclike symptoms were to occur is called (c) ______________. Irrational, marked, and continuous fear of performing in social situations and feeling humiliated or embarrassed is called a (d) ______________.

8. A disorder that consists of persistent, recurring irrational thoughts, impulses, or images that a person is unable to control and irresistible impulses to perform over and over some senseless behavior or ritual is called (a) ______________ disorder. A nondrug treatment for this disorder, which consists of gradually exposing the person to the real anxiety-producing situations or objects that he or she is attempting to avoid, is called (b) ______________ therapy.



9. When something happens to a group of people so that all share the same fears or delusions or develop similar physical symptoms, it is called (a) ______________. There is a disorder that involves a pattern of recurring, multiple, and significant bodily complaints that have no known physical causes. This is called (b) ______________ disorder, and one of its more common forms is somatization disorder.

Answers: *1. mental disorder; 2. (a) genetic, (b) neurological, (c) cognitive-emotional-behavioral, (d) environmental; 3. (a) statistical frequency, (b) social norms, (c) maladaptive behavior; 4. (a) assessment, (b) diagnosis, (c) interview; 5. (a)* Diagnostic and Statistical Manual of Mental Disorders-*IV-TR, (b) diagnosing, (c) communicating, (d) axes; 6. (a) generalized anxiety, (b) panic, (c) panic attack; 7. (a) phobia, (b) specific phobia, (c) agoraphobia, (d) social phobia; 8. (a) obsessive-compulsive, (b) exposure; 9. (a) mass hysteria, (b) somatoform*

F. Cultural Diversity: An Asian Disorder

Taijin Kyofusho, or TKS

Can a culture create a disorder?

Anxiety is a worldwide concern and is the second most common mental disorder in the United States and several Asian nations, notably Japan. The symptoms of one kind of anxiety disorder, somatoform disorder, occur in very similar form in many cultures around the world (Lewis-Fernandez et al., 2005). However, it's also true that the unique cultural values of some countries, such as Japan, can result in the development of a unique anxiety order not found in Western cultures, such as the United States.

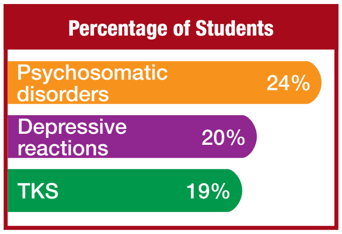
If you had a ***social phobia*** in the United States, it would usually mean that you had a great fear or were greatly embarrassed about behaving or performing in social situations, such as making a public speech. But if you had a social phobia in several Asian cultures, especially Japan and somewhat in Korea, it might mean that you had a very different kind of fear or embarrassment, called taijin kyofusho, or TKS (Tarumi et al., 2004).

In Japan, the fear of offending others (by staring) is considered a kind of social phobia.

Taijin kyofusho *(tai-jin kyo-foo-show),* or TKS, is a kind of social phobia characterized by a terrible fear of offending others through awkward social or physical behavior, such as staring, blushing, giving off an offensive odor, having an unpleasant facial expression, or having trembling hands (Dinnel et al., 2002).

Although many Westerners are also concerned or embarrassed about offending others through staring, having offensive body odors, or blushing, TKS is different in that it is an intense, irrational, morbid fear—in other words, a true phobia. In desperately trying to avoid TKS symptoms, Asians may try to avoid social interactions altogether. The Japanese word ***taijin-kyofu*** literally means "fear of interpersonal relations."

Occurrence. The graph below shows that TKS is the third most common psychiatric disorder treated in Japanese college students (Kirmayer, 1991). TKS is more common in males than in females, with a ratio of about 5:4. Most patients have a primary symptom, which has changed during the past 40 years. Initially, fear of blushing was the primary symptom, but it has been replaced by fear of making eye contact or staring (Yamashita, 1993). In comparison, making eye contact is very common in Western cultures; if you do not make eye contact in social interactions, you may be judged as shy or lacking in social skills.



TKS begins around adolescence, when interpersonal interactions play a big role in one's life. TKS is rarely seen after the late twenties because, by then, individuals have learned the proper social behaviors. TKS seems to develop from certain cultural influences that are unique to Japan.

Cultural values. The Japanese culture places great emphasis on the appropriate way to conduct oneself in public, which means a person should avoid making direct eye contact, staring, blushing, having trembling hands, or giving off offensive odors. To emphasize the importance of avoiding these improper behaviors, mothers often use threats of abandonment, ridicule, and embarrassment as punishment. Through this process of ***socialization,*** the child is made aware of the importance of avoiding improper public behaviors, which result in a loss of face and reflect badly on the person's family and social group. Thus, from early on, Japanese children are strongly encouraged to live up to certain cultural expectations about avoiding improper public behaviors, especially staring and blushing, which are considered to be rude and disgraceful.

Social Customs

In Japan, individuals are expected to know the needs and thoughts of others by reading the emotional expressions of faces rather than asking direct questions, which is considered rude social behavior. In contrast, Westerners may ask direct questions to clarify some point and often use direct eye contact to show interest. Individuals in Japan who make too much eye contact or ask too direct questions are likely to be viewed as insensitive to others, unpleasantly bold, or aggressive. In fact, Japanese children are taught to fix their gaze at the level of the neck of people they are talking to. This Japanese social custom that emphasizes not making eye contact, blushing, or having trembling hands or offensive body odors during social interactions results in about 20% of Japanese teenagers and young adults developing the intense, irrational fear called TKS. This social phobia is so common in Japan that there are special clinics devoted only to treating TKS. The Japanese TKS clinics are comparable in popularity to the numerous weight-loss clinics found in the United States. Interestingly, TKS is a kind of social phobia that doesn't occur in Western cultures (Dinnel et al., 2002; Tarumi et al., 2004).

Cultural differences. Although people in many cultures report anxiety about behaving or performing in public, the particular fears that they report may depend on their own culture's values. For example, TKS is unique to Asian cultures and unknown in Western cultures. Japanese who are especially at risk for developing TKS are those who score low on independence and high on interdependence, two traits found in traditional Japanese cultural values (Dinnel et al., 2002). Clinicians emphasize the importance of taking cultural values, influences, and differences into account when diagnosing behaviors across cultures (Fernando, 2002).

In Japan, it is very important to know and show the proper public behaviors.

Next, we'll discuss a very serious problem in the U.S. culture: school shootings.

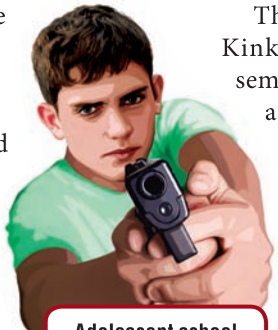
What Drove Teens to Kill Fellow Students and Teachers?

What is their problem?

Sometimes researchers are faced with answering tragic questions, such as why teenagers took guns to schools and shot and killed at least 500 and wounded another 1,000. Everyone wonders what turns these teens into killers. In some cases, but not all, these adolescents might be diagnosed with conduct disorder.

Conduct disorder **refers to a repetitive and persistent pattern of behaving that has been going on for at least a year and that violates the established social rules or the rights of others. Problems may include aggressive behaviors such as threatening to harm people, abusing or killing animals, destroying property, being deceitful, or stealing.**



Adolescent school shooters may have conduct disorder.

The diagnosis of conduct disorder seems to apply to Kipland Kinkel, age 15, who was charged with firing 50 rounds from a semiautomatic rifle into the school cafeteria, killing 2 students and injuring 22. Those who knew him said that Kinkel had a violent temper and a history of behavioral problems, which included killing his cat by putting a firecracker in its mouth, blowing up a dead cow, stoning cars from a highway overpass, and making bombs (Witkin et al., 1998). In trying to answer the question "Why did these adolescents shoot their fellow students and teachers?" mental health professionals have primarily used the case study approach.

A *case study* is an in-depth analysis of the thoughts, feelings, beliefs, experiences, behaviors, and problems of a single individual. We'll give brief case studies of two school shooters and then examine some factors that put a student at risk for becoming a shooter.

Case Studies

The first school shooting that received national attention occurred in Moses Lake, Washington, on February 2, 1996. On that date, Barry Loukaitis, 14, fired on his algebra class, killing three and wounding one. He said that he wanted to get back at a popular boy who had teased him. Loukaitis shot that boy dead. Since then, school shootings have continued at an alarming rate. Across the world, there have been at least 50 adolescents, mostly boys, who took guns to their schools, fired hundreds of shots, killed at least 500 teachers and students, and wounded about 1,000 more (IANSA, 2007).

One such shooter is 23-year-old college student Seung-Hui Cho (below photo), who in 2007 killed 32 people and wounded 25 others on the Virginia Tech campus, making it the deadliest school shooting in history. Cho was born in South Korea and immigrated to the United States when he was 8 years old. As a child, he was relentlessly teased and bullied for being shy and speaking with a strong accent. Consequently, he was isolated and developed anger toward his more "privileged" peers. He came to view himself as an avenger against those who humiliated him (White and affluent). He wanted to get even with the "rich brats" who had trust funds and drove Mercedes. In a disturbing message on the day of his shooting, he stated to the privileged, "You have never felt a single ounce of pain in your whole lives." At the end of his killing spree, Cho took his own life (Gibbs, 2007; Schute, 2007; E. Thomas, 2007).

Seung-Hui Cho committed the deadliest school shooting in history.

Photo Credit: © AP Images/Virginia State Police

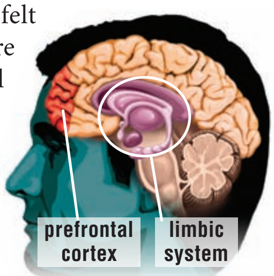
However, very, very few students who are picked on and bullied commit violent acts, such as shooting teachers and students. We'll examine some of the factors that put students as risk for committing violent acts.

Risks Shared by Adolescent School Shooters

Although there are differences among school shooters, researchers have identified a number of risk factors that these boys shared (FBI, 2001; Langman, 2009; R. Lee, 2005; Pollack, 2007; Robertz, 2007; Verlinden et al., 2000).

- Most of the boys (shooters) showed uncontrolled anger and depression, blaming others for problems and threatening violence. Most had poor coping skills, discipline problems at school or home, access to weapons, and a history of drug use.
- Half of the boys had been given little parental supervision, had troubled family relationships, and perceived themselves as receiving little support from their families. Most of the boys had recently experienced the breakup of a relationship, a stressful event, or loss of status.
- Most of the boys were generally isolated and rejected by their peers in school. Most had poor social skills and felt picked on, bullied, and persecuted and made friends who were also antisocial. The most commonly stated motives for shootings were to mete out justice to peers or adults who the teenage shooters believed had wronged them and to obtain status or importance among their peers. Most teenage shooters gave warning signs of their violent intentions that were not taken seriously.

Neurological factors. Although coming from a broken home, being bullied, and dealing with various life stressors are risk factors for adolescents committing violent acts, another important risk factor is inside an adolescent's brain. Everyone gets angry and has felt rage and the desire to get revenge, but most of us are able to control these violent impulses. This control involves the prefrontal cortex (p. 411), which has executive functions, such as planning, making decisions, and controlling strong emotional and violent impulses that arise from a very primitive part of the brain called the limbic system (p. 411) (right figure). The prefrontal cortex in the adolescent brain is still immature and may not reach complete maturity until the early twenties. For this reason, adolescents are especially at risk for committing all kinds of impulsive and violent behaviors and, in extreme cases, even school shootings (Luna, 2006).



Gathering data about what motivates school shooters is an example of using the case study method. Next, we turn to explaining several ways of treating two relatively common anxiety disorders—social and specific phobias.

H. Application: Treating Phobias

Specific Phobia: Flying

At the beginning of this module, we told you about Kate Premo (right photo), who developed a phobia of flying. In some cases, people don't remember what caused their phobias, but Premo remembers exactly when her phobia began. Her fear began as a child when she was on a very turbulent and stressful flight. Her fear was further intensified by her memories of the terrorist bombing of Pan Am flight 103, which killed several of her fellow students. After that incident, her fear of flying turned into a real phobia that kept her from flying to visit friends and family. An estimated 9% of American adults have a phobia of flying called aviophobia, which may include fear of flying, crashing, heights, being in small enclosed spaces, or not having control of the situation (Van Gerwen et al., 1997).

Kate is undergoing exposure therapy for fear of flying.

Most phobias do not disappear without some treatment, and on the few occasions that Premo was forced to fly, she dosed herself with so much alcohol and tranquilizers that she was groggy for days. Finally, she joined a weekend seminar that helps people overcome their fears of flying (M. Miller, 2003). Treatment for phobias can involve psychotherapy or drugs, or some combination of them. We'll discuss psychotherapy and drug treatment, beginning with cognitive-behavioral and exposure therapy.

Cognitive-Behavioral Therapy

Kate's phobia of flying involves fearful and irrational thoughts, which in turn cause increased physiological arousal. She can learn to reduce her irrational and fearful thoughts and reduce her arousal through cognitive-behavioral therapy (Singer & Dobson, 2006).

Cognitive-behavioral therapy involves using a combination of two methods: changing negative, unhealthy, or distorted thoughts and beliefs by substituting positive, healthy, and realistic ones; and changing limiting or disruptive behaviors by learning and practicing new skills to improve functioning.

Thoughts. Cognitive-behavioral therapy is useful in helping Kate control her fearful thoughts and eliminate dangerous beliefs about flying. For example, Kate had learned to fear various noises during flight, which she believed indicated trouble. To change these fearful thoughts, an airplane pilot explained the various noises, such as the thumps meant the landing gear was retracting after takeoff or being put down for landing. Thus, when Kate has a fearful thought, for example, "That noise must mean trouble," she immediately stops herself and substitutes a realistic thought, "That's just the landing gear."

Behaviors. Because Kate automatically gets nervous and fearful when just thinking about flying, she is instructed to do breathing, relaxation, and imagery exercises that will help her calm down. Deep and rhythmic breathing is an effective calming exercise because it distracts Kate from her fears and focuses her attention on a pleasant activity. Relaxing and tensing groups of muscles are also calming and help to decrease physiological arousal. Finally, imagery exercises are calming because focusing on pleasant images is a very powerful way of using her mind to control (relax) her body's fight-flight response.

Cognitive-behavioral methods have proved effective in treating a variety of phobias (Singer & Dobson, 2006). Sometimes cognitive-behavioral therapy is combined with another kind of therapy, called exposure therapy.

Exposure Therapy

For treating phobias, cognitive-behavioral therapy is often combined with exposure therapy. The most difficult part of Kate's phobia treatment is exposure therapy, when she must actually confront her most feared situation.

Exposure therapy consists of gradually exposing the person to the real anxiety-producing situations or objects that he or she is attempting to avoid and continuing exposure treatments until the anxiety decreases.

The first part of Kate's treatment involved cognitive-behavioral therapy, in which she learned how to control her irrational thoughts and acquire some basic relaxation techniques. The second part of her treatment involves exposure therapy, in which she is required to fly on a regularly scheduled airline, meaning that she will be exposed to her most feared situation. To help Kate deal with her fear of flying, Captain Michael Freebairn (photo below) sat next to Kate. Each time Kate tensed or looked fearful, the captain reassured Kate that all was normal and then reminded her to begin relaxation exercises (breathing and relaxing muscles), to use pleasant images, and to substitute positive, healthy thoughts for negative, fearful ones. When the plane landed, Kate was all smiles (left photo) after realizing that exposure therapy had significantly reduced her fear or phobia of flying.

Kate smiles after successfully flying without feeling intense fear.

Programs that treat specific phobias, such as fear of flying, often use some combination of cognitive-behavioral and exposure therapy, which significantly reduces fear in the majority of clients (R. A. Friedman, 2006; M. Miller, 2003).

Clients not helped by cognitive-behavioral or exposure therapy may be given drug therapy (see next page) or they may try virtual reality therapy.

Virtual reality therapy. Although clients never leave the ground, they sit in real airplane seats that vibrate to the sound of airplane engines. Clients wear head-mounted displays that surround them with 3-D experiences of "taking off" and "flying." Everything appears so real that clients who have a fear of flying begin to sweat and their hearts pound just as on real flights. Virtual reality therapy is a kind of exposure therapy, and it can be combined with relaxation exercises and thought substitution and be used to treat a variety of specific phobias, including fear of flying (Rothbaum et al., 2006).

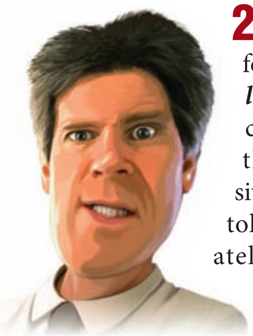
Social Phobia: Public Speaking

When does a fear become a phobia?

Just as specific phobias can be successfully treated with psychotherapy, so too can social phobias, such as public speaking. Almost everyone is somewhat anxious about getting up and speaking in public. For a fear to become a full-blown phobia, however, the fear must be intense, irrational, and out of all proportion to the object or situation. For example, individuals with social phobias have such intense, excessive, and irrational fears of doing something humiliating or embarrassing that they will go to almost any lengths to avoid speaking in public. There are a number of very effective nondrug programs for treating social phobias (fear of speaking, performing, or acting in public). These programs combine cognitive-behavioral and exposure therapies and usually include the following four components (M. E. Coles & Horng, 2006).

1 Explain. Clinicians ***explain*** to the person that, since the fears involved in social phobias are usually learned, there are also methods to unlearn or extinguish such fears. The person is told how both thoughts and physiological arousal can exaggerate the phobic feelings and make the person go to any lengths to avoid the feared situation.



Treating social phobias involves four components.

2 Learn and substitute. Clinicians found that some individuals needed to ***learn*** new social skills (initiating a conversation, writing a speech) so that they would function better in social situations. In addition, individuals were told to record their thoughts immediately after thinking about being in a feared situation. Then they were shown how to ***substitute*** positive and healthy thoughts for negative and fearful ones.

3 Expose. Clinicians first used ***imaginary exposure,*** during which a person imagines being in the situation that elicits the fears. For example, some individuals imagined presenting material to their co-workers, making a classroom presentation, or initiating a conversation with the opposite sex. After imaginary exposure, clinicians used ***real (in vivo) exposure,*** in which the person gives his or her speech in front of a group of people or initiates conversations with strangers.

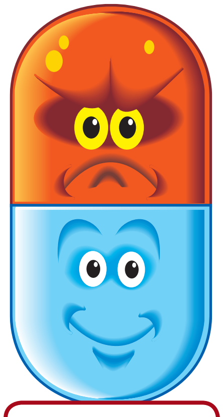
4 Practice. Clinicians asked subjects to ***practice*** homework assignments. For instance, individuals were asked to imagine themselves in feared situations and then to eliminate negative thoughts by substituting positive ones. In addition, individuals were instructed to gradually expose themselves to making longer and longer public presentations or having conversations with the opposite sex.

Researchers report that programs similar to the one above resulted in reduced social fears in about 56% of those who completed the program (Lincoln et al., 2003).

Drug Treatment of Phobias

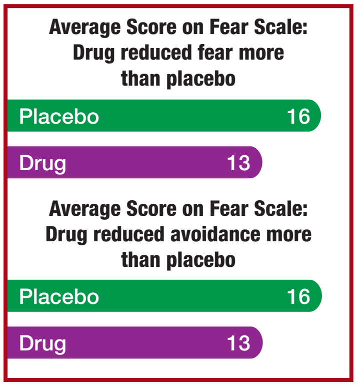
How effective are drugs?

Imagine being told to walk into a room and meet a group of strangers while you are stark naked. For most of us, this idea would cause such embarrassment, fear, and anxiety that we would absolutely refuse. This imagined situation is similar to the terrible negative emotions that individuals with social phobia feel when they must initiate a conversation, meet strangers, or give a public presentation. As we have discussed, social phobias can be treated with cognitive-behavioral and exposure therapy. However, some individuals with social phobia do not choose to or are too fearful to complete a therapy program that includes exposure to the feared situation. Instead, these individuals may choose drug therapy, which may involve tranquilizers (benzodiazepines) or the increasingly prescribed antidepressants (Blanco et al., 2003; M. E. Coles & Horng, 2006).



Drug therapy for phobias involves tranquilizers or antidepressants.

The graphs below show the results of a double-blind study in which individuals with social phobia were given either a placebo or an antidepressant, in this case sertraline (Zoloft). After 20 weeks of treatment, individuals given antidepressants showed a significant clinical reduction in scores on both anxiety and fear tests, which means they were able to function relatively well in social situations (Van Ameringen et al., 2001). Although 34% of those on antidepressants showed a significant decrease in social anxiety, a remarkable 18% of those given placebos (sugar pills) showed a similar decrease. This means that the significant decrease in the social fears of almost one out of five individuals resulted from purely psychological factors, such as a client's expectations and beliefs ("The pill is powerful medicine and will reduce my fear").



Although drug treatments are effective in reducing social phobias, there are two potential problems. First, about 50–75% of individuals relapse when drugs are discontinued, which means that their original intense social phobic symptoms return. Second, long-term maintenance on drugs can result in tolerance and increases in dosage, which, in turn, can result in serious side effects, such as loss of memory (S. M. Stahl, 2000, 2002). Compared to drug treatment of phobias, psychotherapy programs have the advantages of no problems with tolerance and no unwanted physical side effects.

Which treatment to choose? Whether a client chooses psychotherapy or drug treatment for phobias depends to a large extent on each individual client's preference. That's because drug treatment (tranquilizers or antidepressants) and cognitive-behavioral or exposure therapy are about equally effective in the treatment of different phobias, including specific phobias, social phobias, and agoraphobia (Liebowitz et al., 1999).

Summary Test

A. Factors in Mental Disorders

1. A prolonged or recurring problem that seriously interferes with an individual's ability to live a satisfying personal life and function in society is a _______________. This definition takes into account genetic, behavioral, cognitive, and environmental factors, all of which may contribute to a mental disorder.

2. Mental disorders arise from the interaction of a number of factors. Biological factors include inherited behavioral tendencies, which are called (a) _______________ factors. These factors contribute from 30% to 60% to the development of mental disorders. Biological factors also include the overreaction of brain structures to certain stimuli, which are called (b) _______________ factors. Other factors that contribute to the development of mental disorders, such as deficits or problems in thinking, processing emotional stimuli, and social skills, are called (c) _______________ factors. Being in or seeing a traumatic event, which is called an (d) _______________ factor, can contribute to developing a mental disorder such as PTSD.

3. If a behavior is considered abnormal because it occurs infrequently in the general population, we are using a definition based on (a) _______________ frequency. If a behavior is considered abnormal because it deviates greatly from what's acceptable, we are using a definition based on (b) _______________. If a behavior is considered abnormal because it interferes with an individual's ability to function as a person or in society, we are using a definition based on (c) _______________ behavior.

B. Assessing Mental Disorders

4. A systematic evaluation of an individual's various psychological, biological, and social factors that may be contributing to his or her problem is called a (a) _______________. The primary method used in clinical assessments is to get information about a person's background, current behavior, attitudes, and emotions and also details of present problems through a (b) _______________. A complete clinical assessment usually includes three major methods: (c) _______________, _______________, and _______________.

5. Assessing mental disorders may be difficult because (a) _______________ vary in intensity and complexity. The assessment must take into account past and present problems and current stressors. The accurate assessment of symptoms is important because it has significant implications for the kind of (b) _______________ that the client will be given.

C. Diagnosing Mental Disorders

6. When mental health professionals determine whether an individual's specific problem meets or matches the standard symptoms that define a particular mental disorder, they are making a (a) _______________. In trying to reach an agreement on the clinical diagnosis, mental health professionals use a set of guidelines, developed by the American Psychiatric Association, called the (b) _______________, which is abbreviated as DSM-IV-TR.

7. The DSM-IV-TR is a set of guidelines that uses five different dimensions or (a) _______________ to diagnose mental disorders. The advantage of the DSM-IV-TR is that it helps mental health professionals communicate their findings, conduct research, and plan for treatment. One disadvantage of using the DSM-IV-TR to make a diagnosis is that it places people into specific categories that may have bad associations; this problem is called (b) _______________.

D. Anxiety Disorders

8. A mental disorder that is marked by excessive and/or unrealistic worry or feelings of general apprehension about events or activities, when those feelings occur on a majority of days for a period of at least six months, is called _______________. This anxiety disorder is treated with some form of psychotherapy and/or drugs known as benzodiazepines.

9. One mental disorder is characterized by recurring and unexpected panic attacks and continued worry about having another panic attack; such worry interferes with psychological functioning. This problem is called a _______________ disorder.

10. Suppose you experience a period of intense fear or discomfort in which four or more of the following symptoms are present: pounding heart, sweating, trembling, shortness of breath, feelings of choking, chest pain, nausea, feeling dizzy, and fear of losing control or dying. You are having a (a) _______________. Panic disorders are treated with a combination of benzodiazepines or antidepressants and (b) _______________.

11. Another anxiety disorder characterized by increased physiological arousal and an intense, excessive, and irrational fear that is out of all proportion to the danger elicited by the object or situation is called a _______________.

12. The DSM-IV-TR divides phobias into three categories. Those that are triggered by common objects, situations, or animals (such as snakes or heights) are called (a) _______________ phobias.

Photo Credits: (#1) © *San Diego Union Tribune*/ZUMA Press; (#4) © AP Images/Ruth Fremson

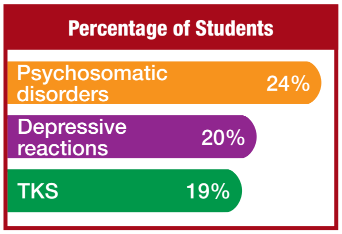
Those that are brought on by having to perform in social situations and expecting to be humiliated and embarrassed are called (b) ________________ phobias. Those that are characterized by fear of being in public places from which it may be difficult or embarrassing to escape if panic symptoms occur are called (c) ________________. Once established, phobias are extremely persistent and may require treatment.

13. Persistent, recurring irrational thoughts that a person is unable to control and that interfere with normal functioning are called (a) ________________. Irresistible impulses to perform some ritual over and over, even though the ritual serves no rational purpose, are called (b) ________________. A disorder that consists of both of these behaviors and that interferes with normal functioning is called (c) ________________. The most effective nondrug treatment for obsessive-compulsive disorder is (d) ________________ therapy.

E. Somatoform Disorders

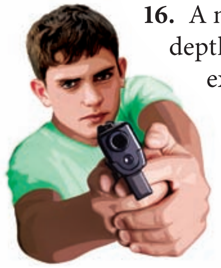
14. The appearance of real physical symptoms and bodily complaints that are not under voluntary control, have no known physical causes, extend over several years, and are believed to be caused by psychological factors is characteristic of (a) ________________ disorders. The DSM-IV-TR lists seven kinds of somatoform disorders. The occurrence of multiple symptoms—including pain, gastrointestinal, sexual, and neurological symptoms—that have no physical causes but are triggered by psychological problems or distress is referred to as (b) ________________ disorder; a disorder characterized by unexplained and significant physical symptoms or deficits that affect voluntary motor or sensory functions and that suggest a real neurological or medical problem is called a (c) ________________ disorder. A recent survey reported that somatoform disorders occur worldwide, although their symptoms may differ across cultures.

F. Cultural Diversity: An Asian Disorder



15. A social phobia found in Asia, especially Japan, that is characterized by morbid fear of making eye-to-eye contact, blushing, giving off an offensive odor, having an unpleasant or tense facial expression, or having trembling hands is called ________________. This phobia appears to result from Asian cultural and social influences that stress the importance of showing proper behavior in public.

G. Research Focus: School Shootings



16. A method of investigation that involves an in-depth analysis of the thoughts, feelings, beliefs, experiences, behaviors, or problems of a single individual is called a (a) ________________. This method was used to decide if teenage school shooters had repetitive and persistent patterns of behavior that had been going on for at least a year and involved threats or physical harm to people or animals, destruction of property, being deceitful, or stealing. These symptoms define a mental disorder that is called (b) ________________.

H. Application: Treating Phobias

17. There are several different treatments for phobias. A nondrug treatment combines changing negative, unhealthy, or distorted thoughts and beliefs by substituting positive, healthy, and realistic ones and learning new skills to improve functioning; this treatment is called (a) ________________ therapy. Another therapy that gradually exposes the person to the real anxiety-producing situations or objects that he or she has been avoiding is called (b) ________________ therapy. Individuals who are unwilling or too fearful to be exposed to fearful situations or objects may choose drug therapy.

18. Social and specific phobias have been successfully treated with tranquilizers called (a) ________________. Although these drugs are effective, they have two problems: When individuals stop taking these drugs, the original fearful symptoms may return, which is called (b) ________________; and, if individuals are maintained on drugs for some length of time, they may develop tolerance, which means they will have to take larger doses, which in turn may cause side effects such as loss of (c) ________________. Researchers found that drug therapy was about equally effective as cognitive-behavioral or exposure therapy in reducing both social and specific phobias, including agoraphobia.

Answers: *1. mental disorder; 2. (a) genetic, (b) neurological, (c) cognitive-emotional-behavioral, (d) environmental; 3. (a) statistical frequency, (b) social norms, (c) maladaptive behavior; 4. (a) clinical assessment, (b) clinical interview, (c) clinical interview, psychological tests, neurological tests; 5. (a) symptoms, (b) treatment; 6. (a) clinical diagnosis, (b)* Diagnostic and Statistical Manual of Mental Disorders-*IV-TR; 7. (a) axes, (b) labeling; 8. generalized anxiety; 9. panic; 10. (a) panic attack, (b) psychotherapy; 11. phobia; 12. (a) specific, (b) social, (c) agoraphobia; 13. (a) obsessions, (b) compulsions, (c) obsessive-compulsive disorder, (d) exposure; 14. (a) somatoform, (b) somatization, (c) conversion; 15. taijin kyofusho, or TKS; 16. (a) case study, (b) conduct disorder; 17. (a) cognitive-behavioral, (b) exposure; 18. (a) benzodiazepines, (b) relapse, (c) memory*

Why Women Marry Killers behind Bars

In 2004, Scott Peterson was convicted of murdering his wife and unborn child. Within an hour of being on Death Row, he received a marriage proposal from a woman he didn't even know. As if this proposal wasn't bizarre enough, on Scott's first day at San Quentin State Prison, the warden's office received calls from over 30 women desperate to make contact with the convicted killer, many of them believing they were in love with Peterson.

A woman fell in love with a convicted and jailed killer.

About a decade earlier, Doreen Lioy, a 41-year-old woman, fell in love with satanic serial killer Richard Ramirez, who was convicted of torturing, sexually abusing, and murdering 13 people. Lioy described her attraction to Ramirez beginning immediately upon seeing his mug shot on TV: "I saw something in his eyes. Something that captivated me" (Warrick, 1996, E-1). Lioy began sending Ramirez letters and visiting him behind bars, and soon after they married at the prison, even though Ramirez would eventually be executed. Lioy speaks about her complete devotion to her new husband: "Because of my love for Richard, I have given up my family, home, employment, and friends" (Warrick, 1996, E-1).

There is such a demand for prisoner romance that matchmaking websites, such as prisonpenpals.com, offer thousands of ads from inmates who want to find love outside of their cellblocks. Marriages in prisons are common enough for each prison to have its own set of regulations for inmate marriages. Some of the rules for one California prison include: "No property will be exchanged and kept by inmate after the marriage ceremony. The marriage ceremony will be conducted in the visiting area with the glass separating the couple being married" ("Inmate marriages," 2007).

According to Sheila Isenberg, author of *Women Who Marry Men Who Kill,* women who pursue intimate relationships with killers are usually attractive, intelligent, and very well accomplished. Isenberg also says most of these women have come from loveless homes and have been abused by men earlier in their lives. Gilda Carle, a relationship adviser, explains that these women are attracted to the "bad boy syndrome" and they feel special when the man who has hurt and killed others treats them with love, kindness, and respect. In fact, the most repugnant murderers receive the most attention from women.

Women in love with convicted killers find the danger, excitement, and drama of prison romance more arousing than the routine and predictability of romance outside prison. Having an intimate relationship with a man behind bars also makes the relationship exceptionally safe. (Adapted from Fimrite & Taylor, 2005; "Inmate marriages," 2007; Warrick, 1996, 1997; Wiltenburg, 2003)

QUESTIONS

1 How would clinicians decide if women who fall in love with killers have a mental disorder?

2 Do women who almost instantly fall in love with prisoners they have never met have obsessive-compulsive disorder?

3 According to the three definitions of abnormal behavior, is Doreen Lioy abnormal?

4 According to Freud's psychodynamic theory of personality, why is it difficult to explain why women fall in love with and marry killers?

5 Which of the five axes in the DSM-IV-TR best describes the problems these women share?

6 What are the advantages and disadvantages of labeling these women's problems?

Suggested Answers to Critical Thinking

1. Clinicians would use a clinical assessment (neurological and psychological/personality tests and interviews) to identify symptoms and then match symptoms to the mental disorders listed in the DSM-IV-TR.
2. These women may have obsessions, which are persistent, irrational thoughts, but there is no indication that the obsessions cause marked anxiety or that the women engage in compulsions, which are irresistible, senseless behaviors or rituals.
3. A woman who falls in love with a convicted killer after seeing his mug shot and pursues him even though he will never be able to leave prison is certainly abnormal in terms of statistical frequency, in terms of deviation from social norms, and in terms of engaging in maladaptive behavior (giving up family, home, work, friends).
4. According to Freud's psychodynamic theory of personality, women who fall in love with and marry killers are influenced by unconscious forces, wishes, and repressed desires, which are difficult to examine and understand because they are unconscious and not easily revealed or brought to the surface.
5. To identify potential problems of women who fall in love with killers, clinicians might use Axis II, which focuses on long-standing personality traits that are maladaptive or impair functioning.
6. One advantage of labeling these women's problem is that it may help decide which therapy is best. One disadvantage is that giving women a label may bias how others perceive and respond to her.

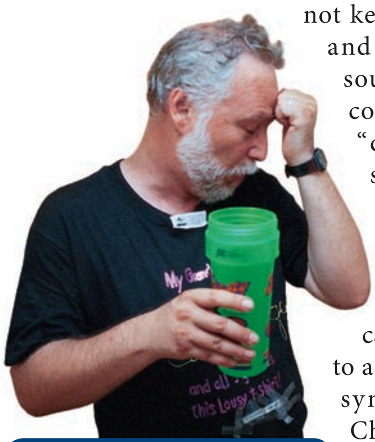
Mood Disorder

Why do his thoughts speed up?

Chuck Elliot (photo below) was checking out the exhibits at an electronics convention in Las Vegas when suddenly his mind seemed to go wild and spin at twice its regular speed. His words could not keep up with his thoughts, and he was talking in what sounded like some strange code, almost like rapid fire "dot, dot, dot." Then he stripped off all his clothes and ran stark naked through the gambling casino of the Hilton Hotel. The police were called, and Chuck was taken to a mental hospital. After his symptoms were reviewed, Chuck was diagnosed with what was then called manic depression.



Chuck Elliot's mind spins and whirls out of control. He was diagnosed with having bipolar I disorder.

At one time, Chuck had a very successful career. After taking postgraduate courses, he obtained a doctor of education degree (Ed.D.). He started and ran his own video production business while also designing computer software. But since that first strange episode at the computer electronics convention, Chuck has been hospitalized about twice a year when his mind races and spins wildly out of control in what are called manic episodes. He usually takes medication, but because the drug slows him down more than he likes, he stops taking his medication every so often. Without medication, his energy may come back with such force that it blasts him into superactive days and sleepless nights, and he often ends up in a psychiatric hospital.

His last regular job ended when he was in the middle of another manic attack. He was going on 100 hours without sleep when he went out to his car, grabbed a bunch of magazines, books, fruits, and vegetables, and piled them all on the desk in his office. When his boss came by and found a desk piled high with junk and Chuck sitting there with his mind spinning, the boss fired him on the spot (C. Brooks, 1994). Since that time, despite his very good academic, computer, and business qualifications, he has not been able to hold a steady job.

More recently, Chuck married a woman he had been dating for only ten days. She understands Chuck very well because she too is manic-depressive and has similar mental health problems. She hopes that they can care for each other. She says, "Chuck is the most brilliant man I have ever met. I am so lucky" (C. Brooks, 1994, p. 4).

In this module, we'll explain Chuck's illness, his treatment, and how he is dealing with his problem.

Schizophrenia

Why was he hearing voices?

When Michael McCabe was 18 years old, Marsha, his mother, thought that he was just about over his rebellious phase. She was looking forward to relaxing and enjoying herself. But then Michael said that he was hearing voices. At first Marsha thought that Michael's voices came from his smoking marijuana. But the voices persisted for two weeks, and Marsha checked Michael into a private drug treatment center. He left the center after 30 days and seemed no better off than he had been before. Several days later, Marsha found Michael in her parents' home, a couple of miles down the road from her own house. Michael was sitting on the floor, his head back, holding his throat and making grunting sounds like an animal. Marsha got really scared and called the police, but before they arrived, Michael ran off.

Michael spent time with his grandparents, who finally called Marsha and said that they couldn't take his strange behavior anymore. Once again Marsha called the police. Just as Michael (photo below) tried to run away, the police caught him and took him to the community psychiatric hospital.

Michael McCabe, 18 years old, began hearing voices and was diagnosed with having schizophrenia.

Marsha received a call from a psychiatrist at the hospital, who explained that Michael had been diagnosed as having schizophrenia, a serious mental disorder that includes hearing voices and having disoriented thinking. A few days later, Michael escaped from the hospital. He was later returned by police, put into leather restraints, and given antipsychotic drugs that would also calm him down. Michael remained in the hospital and was treated with drugs for about a month, with little success.

Just about the time Marsha was at her wits' end about what to do next, Michael was put on a new antipsychotic drug, clozapine. After about a month on the new drug, Michael improved enough to be discharged back into Marsha's care (C. Brooks, 1994, 1995a).

In this module, we'll explain what schizophrenia is, describe the drugs Michael was given, and report how his treatment is working.

What's Coming

We'll discuss several different mental disorders and their treatments. We'll explain mood disorders and their treatments, including the treatment of last resort for depression, electroconvulsive shock therapy. We'll also examine several personality disorders and different kinds of schizophrenia, along with old and new antipsychotic drugs. We'll end with a group of strange and unusual disorders, one of which is multiple personality disorder.

We'll begin with Chuck Elliot's problem, which is an example of one kind of mood disorder.

A. Mood Disorders

Kinds of Mood Disorders

How bad is it?

Depression is not choosy; it happens to about 6 million Americans a year. Major depression is one example of a mood disorder.

A ***mood disorder*** is a prolonged and disturbed emotional state that affects almost all of a person's thoughts, feelings, and behaviors.

Most of us have experienced a continuum of moods, with depression on one end and elation on the other. However, think of the depression or blues that most of us feel as having a paper cut on our finger. Then major depression is more like having to undergo open-heart surgery. It's some of the worst news that you can get.

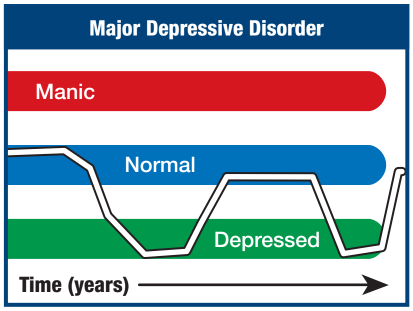
The DSM-IV-TR lists ten different mood disorders, but we'll focus on the symptoms of three of the more common forms: major depressive disorder, bipolar I disorder, and dysthymic disorder.

Major Depression

Popular singer-songwriter Sheryl Crow (photo below) says that she has battled major depression most of her life.

Major depressive disorder is marked by at least two weeks of continually being in a bad mood, having no interest in anything, and getting no pleasure from activities. In addition, a person must have at least four of the following symptoms: problems with eating, sleeping, thinking, concentrating, or making decisions, lacking energy, thinking about suicide, and feeling worthless or guilty (American Psychiatric Association, 2000).

Sheryl Crow says that she had been on a world tour with Michael Jackson, singing in front of 70,000 screaming fans. When the tour ended, she was back in her lonely apartment with the anxiety of having to get a record contract. All this stress triggered her first bout of depression, which resulted in her lying in bed, hardly able to move, going unshowered, stringy-haired, and ordering take-out for seven straight months (Hirshey, 2003). Like Crow, about 16% of U.S. adults reported at least one lifetime episode of major depression, with women outnumbering men by a ratio of 2 to 1 (Thase, 2006).



To help understand mood disorders, look at the graph above, which shows three general mood states. The top bar shows a manic episode or period of incredible energy and euphoria that we'll discuss later. The middle bar shows a normal period when a person's moods and emotions do not interfere with normal psychological functioning. However, like what happened to Crow, some event may cause a person to go from a normal period to a period of depression (bottom bar). Individuals may fluctuate between a normal period and a bout of severe depression.

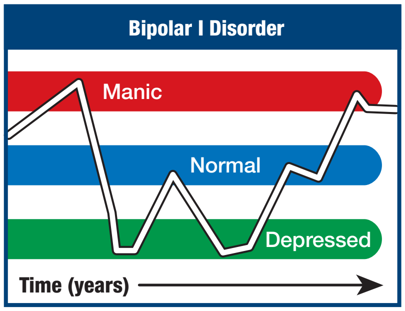
Bipolar I Disorder

Unlike Sheryl Crow, who has a major depressive disorder, Chuck Elliot (right photo) fluctuates between two extreme moods of depression and mania; he has what is called bipolar I disorder.

Bipolar I disorder is marked by fluctuations between episodes of depression and mania. A manic episode goes on for at least a week, during which a person is unusually euphoric, cheerful, and high and has at least three of the following symptoms: has great self-esteem, has little need for sleep, speaks rapidly and frequently, has racing thoughts, is easily distracted, and pursues pleasurable activities (American Psychiatric Association, 2000).

About 1.3% of the population suffer from bipolar I disorder, and 1.6% suffer from only manic episodes (Rush, 2003).

Chuck Elliot has the typical pattern of bipolar I disorder. As shown in the graph below, Elliot may have periods of being normal, which may turn into extreme manic episodes followed by periods of extreme depression.



Dysthymic Disorder

Another mood disorder that is less serious than major depression is called dysthymic *(dis-THY-mick)* disorder.

Dysthymic disorder is characterized by being chronically but not continuously depressed for a period of two years. While depressed, a person experiences at least two of the following symptoms: poor appetite, insomnia, fatigue, low self-esteem, poor concentration, and feelings of hopelessness (American Psychiatric Association, 2000).

Individuals with dysthymic disorder, which affects about 6% of the population, are often described as "down in the dumps." Some of these individuals become accustomed to such feelings and describe themselves as "always being this way."

Besides these three mood disorders, we have also discussed another mood disorder, seasonal affective disorder, or SAD (p. 159). People with SAD become depressed as a result of a decrease in the number of sunny days, such as occurs in fall and winter months, and they recover with the arrival of summer.

Next, we'll examine some of the common causes of mood disorders.

Photo Credits: left, © Evan Agostini/Getty Images; center, © Robert Gauthier

Causes of Mood Disorders

Sheryl Crow says that she has had a lifetime battle with mood disorders and, contrary to popular myths, when depressed she cannot make great music or work much at anything. Crow thought her depression was due to some chemical imbalance in her brain and that depression ran in families (partly inherited or genetic) because her father suffered from similar mood problems (Hirshey, 2003). Let's see if she's right.

What caused Crow's depression?

Biological Factors

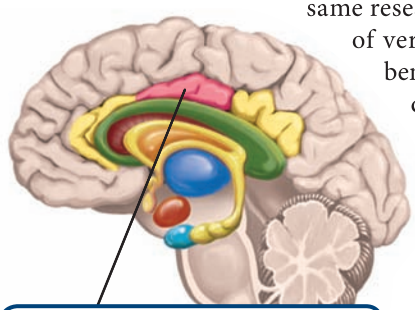
Using recently developed techniques for studying the living brain and information from mapping the genetic code (Human Genome Project—p. 68), researchers have been actively studying biological factors involved in mood disorders.

Biological factors underlying depression are genetic, neurological, chemical, and physiological components that may predispose or put someone at risk for developing a mood disorder.

Genetic factors. Sheryl Crow was right about depression having a genetic component. Research studies comparing depression rates of identical twins with those of fraternal twins, who share only 50% of their genes, find that 40–60% of each individual's susceptibility to depression is explained by genetics (Canli, 2008). Researchers believe there is no single gene but rather a combination of genes that produces a risk, or predisposition, for developing a mood disorder (B. Bower, 2009b; Levinson, 2009). One theory states that defects in specific genes affect our sensitivity to stress, which can result in depression (D. R. Weinberger, 2005). Genes play a role in developing a mood disorder because genes are involved in regulating the brain's neurotransmitter or chemical system used for communication (Canli, 2008).

Neurological factors. Sheryl Crow was also right about depression involving a chemical imbalance in her brain. A group of neurotransmitters, called the ***monoamines*** (serotonin, norepinephrine, and dopamine), are known to be involved in mood problems. Abnormal levels of certain neurotransmitters can interfere with the functioning of the brain's communication networks and, in turn, put individuals at risk for developing mood disorders. More recently, researchers discovered that continued stress causes the brain and the body's stress management machinery (p. 485) to go into overdrive, which in turn alters hormonal and neurotransmitter levels and can trigger depression (Thase, 2009).

Brain scans. Researchers took computerized photos of the structure and function of living brains and compared brains of depressed patients with those of individuals with normal moods. Researchers reported that a brain area called the anterior cingulate cortex (figure below) was overactive in very depressed patients. When the anterior cingulate cortex is overactive, it allows negative emotions to overwhelm thinking and mood. These same researchers cured two-thirds of a group of very depressed patients who had not benefitted from years of psychotherapy, drugs, or electroconvulsive therapy (p. 535) by electrically stimulating the brain, which led to reduced activity in the anterior cingulate cortex (Mayberg, 2006; Mayberg et al., 2005). This and other research examining the brains of depressed patients suggest that faulty brain structure or function contributes to the onset and/or maintenance of mood disorders (Thase, 2009).



The anterior cingulate cortex is overactive in very depressed patients, which allows negative emotions to overwhelm thoughts and mood.

Psychosocial Factors

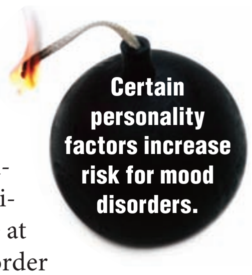
In addition to biological factors, an individual may be at risk for depression because of psychosocial factors.

Psychosocial factors, such as personality traits, cognitive styles, social supports, and the ability to deal with stressors, interact with predisposing biological factors to put one at risk for developing a mood disorder.

Stressful life events. Sheryl Crow says that her period of depression was triggered by the overwhelming stress of seeing a fantastic world tour end with her living in a lonely apartment, having to wait on tables while struggling to get a record contact. Researchers found that stressful life events are strongly related to the onset of mood disorders such as depression (Kendler et al., 2004).

Negative cognitive style. There is considerable research to support Aaron Beck's (1991) idea that depression may result from one's perceiving the world in a negative way, which in turn leads to feeling depressed. We'll discuss Beck's theory later in the Application, but just note here that having a negative cognitive style or ***negative way of thinking*** and perceiving can put one at risk for developing a mood disorder such as depression.

Personality factors. Individuals who are especially sensitive to and ***overreact to negative events*** (rejections, criticisms) with feelings of fear, anxiety, guilt, sadness, and anger are at risk for developing a mood disorder (D. N. Klein et al., 2002). Researchers also found that individuals who make their self-worth primarily dependent on what others say or think have a kind of ***socially dependent personality,*** which puts them at risk for becoming seriously depressed when facing the end of a close personal relationship or friendship. Some individuals have a ***need for control,*** which puts them at risk for depression when they encounter uncontrollable stress (Mazure et al., 2000).



Certain personality factors increase risk for mood disorders.

Depressed mothers. Research shows that a depressed mother significantly increases her child's susceptibility to depression, even if the child is adopted and shares no genes with the mother. Also, when depressed mothers receive successful treatment, their depressed children experience mood improvement without receiving therapy themselves (B. Bower, 2008c; Tully et al., 2008).

The above psychosocial factors interact with underlying biological factors to increase one's risk of developing a mood disorder (Thase, 2006).

Next, we discuss the treatment for depression.

A. Mood Disorders

Treatment of Mood Disorders

What's the treatment?

Because the causes of depression include both biological and psychosocial factors, the treatment for depression, depending upon the diagnosis and severity, may include psychotherapy, antidepressant drugs, or both. We'll discuss the effectiveness of drugs and psychotherapy.

Major Depression and Dysthymic Disorder

After months of depression, Sheryl Crow's mother finally persuaded her (with threats of coming to haul her baby out of bed) to get professional treatment, which involved both psychotherapy and antidepressant drugs.

Treatment often requires professional help.

Antidepressant drugs act by increasing the levels of a specific group of neurotransmitters (monoamines—serotonin, norepinephrine, and dopamine) that are involved in the regulation of emotions and moods.

Selective serotonin reuptake inhibitors—SSRIs. About 80% of prescribed antidepressant drugs, such as Prozac and Zoloft, belong to a group of drugs called ***SSRIs*** (selective serotonin reuptake inhibitors) (Noonan & Cowley, 2002). The SSRIs work primarily by raising the level of the neurotransmitter serotonin. Common side effects include nausea, insomnia, sedation, and sexual problems (decreased libido, erectile dysfunction) (Gitlin, 2009; Khawam et al., 2006). Antidepressants have recently become the most commonly prescribed medication in the United States, used by 10% of the population (Olfson & Marcus, 2009).

Effectiveness of antidepressants. When depressed patients use an antidepressant, which may take up to 8 weeks to work, symptoms for only one-third of the patients will go away (comparable to the recovery rate for a placebo) (Berenson, 2006). The challenge for physicians prescribing antidepressants is that for any given individual, some antidepressants work better than others, but no one antidepressant has been found to be more effective for everyone. Often, patients must try a second or third antidepressant until they find one that works well and has minimal side effects (Arkowitz & Lilienfeld, 2007b).

Psychotherapy. Researchers compared patients who had received antidepressant drugs, psychotherapy, or a combination of drugs and psychotherapy to treat major depression. For patients with less severe depression, psychotherapy was as effective as antidepressant drugs. For patients with more severe depression, a combination of antidepressant drugs (SSRIs) and psychotherapy was more effective than either treatment alone (Hollon et al., 2002).

Relapse. When patients who had recovered were followed for 18 months, the results were discouraging because, within that time, 70% of the patients had relapsed, which means they became depressed again and required additional treatment. Of those who maintained their recovery and were doing well, 30% had been treated with psychotherapy, 20% with antidepressant drugs, and 20% with placebos. Thus, patients treated with psychotherapy were somewhat less likely to relapse than those treated with drugs or placebos (Shea et al., 1992). Psychotherapy may take longer to begin working, but its strength is in reducing the likelihood of relapse (Charney, 2009).

Antidepressants and psychotherapy are about equally effective.

Because 70% of patients treated for depression relapse within 18 months and 82% relapse during the first five years, clinicians concluded that major depression is a long-term or chronic disorder that may require further treatments during the patient's lifetime (Moran, 2004; Vos et al., 2004).

Bipolar I Disorder

Unlike Sheryl Crow's problem, which is major depressive disorder, Chuck Elliot has bipolar I disorder, which means he cycles between episodes of depression and mania. For example, one of Elliot's manic episodes lasted four days, during which he was in almost constant motion and did not sleep. Several times, when he lost control, he screamed at his wife and ripped the blinds from the windows. His wife called the police, who handcuffed Elliot (right photo) and drove him to a psychiatric hospital for drug treatment.

Bipolar I is treated with lithium and other drugs.

Treatment. In the past, the drug of choice to treat bipolar I disorder was a mood stabilizer called lithium *(LITH-ee-um)*. Although still used today as the drug of choice, lithium is often combined with other drugs, including antipsychotics and antidepressants, which offer a more effective long-term treatment program (C. F. Newman, 2006).

Lithium is thought to prevent manic episodes by preventing neurons from being overstimulated (Lenox & Hahn, 2000). When Elliot takes medication, he functions well enough that he has enrolled in law school and is working toward his degree. The problem arises when Elliot doesn't take lithium. When patients with bipolar I disorder stop taking lithium (and combined drugs), about 50% experience a manic episode (P. E. Keck & McElroy, 2003). In terms of effectiveness, 50% of bipolar patients are greatly helped with a combined drug program (lithium plus other drugs), 30% are partially helped, and 20% get little or no help (F. K. Goodwin, 2003).

Mania. Lithium has been found to be effective in treating individuals with ***mania***—that is, the manic episodes without the depression (F. K. Goodwin, 2003). Because lithium prevents mania, patients may stop taking it to experience the euphoria they miss, as Elliot did several times.

Relapse. For both major depression and bipolar I disorder, 10–30% of patients receive no help from current drugs and 30–70% initially improve but later relapse. Researchers are constantly searching for new ways to treat mood disorders and prevent relapse.

For individuals with major depression who are not helped by drugs, there is something called the treatment of last resort.

B. Electroconvulsive Therapy

Definition and Usage

What's it like to get ECT?

Because the use of shock as therapy has often been portrayed incorrectly in the media, it helps to see the treatment from the eyes of an actual patient.

Electrodes on this patient's forehead will carry electricity through the brain and cause a major seizure.

"…As far as manic-depressive tales go, my stories are typical. My illness went undiagnosed for a decade, a period of euphoric highs and desperate lows highlighted by $25,000 shopping sprees, impetuous trips to Tokyo, Paris, and Milan, drug and alcohol binges…. After seeing eight psychiatrists, I finally received a diagnosis of bipolar disorder on my 32nd birthday. Over the next year and a half, I was treated unsuccessfully with more than 30 medications. My suburban New Jersey upbringing, my achievements as a film major at Wesleyan, and a thriving career in public relations couldn't help me…. As a last resort, I'm admitted to the hospital for ECT, electroconvulsive therapy, more commonly known as electroshock…. The doctor presses a button. Electric current shoots through my brain for an instant, causing a grand-mal seizure for 20 seconds…. I wake up 30 minutes later and think I'm in a hotel room in Acapulco. My head feels as if I've just downed a frozen margarita too quickly…. After four treatments, there is marked improvement. No more egregious highs or lows. But there are huge gaps in my memory. I avoid friends and neighbors because I don't know their names anymore. I can't remember the books I've read or the movies I've seen. I have trouble recalling simple vocabulary. I forget phone numbers…. But I continue treatment because I'm getting better…. On the one-year anniversary of my first electroshock treatment, I'm clearheaded and even-keeled. I call my doctor to announce my 'new and improved' status…. Two and a half years later, I still miss ECT. But medication keeps my illness in check, and I'm more sane than I've ever been" (Behrman, 1999, p. 67).

This patient received electroconvulsive therapy (ECT).

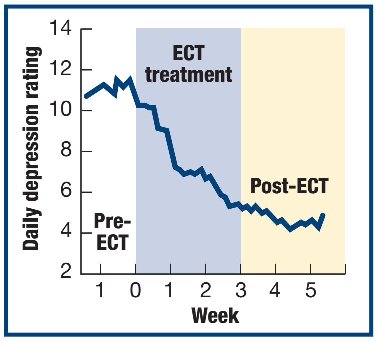
Electroconvulsive therapy, **or** ***ECT,*** **involves placing electrodes on the skull and administering a mild electric current that passes through the brain and causes a seizure. Usual treatment consists of a series of 10 to 12 ECT sessions, at the rate of about three per week.**

Usage. Because antidepressants fail to decrease depression in up to 40% of patients, many of these patients choose to undergo ECT, a last resort option to treat their severe depression. In the United States, ECT is currently used for 100,000 patients per year (Gitlin, 2009; *Newsweek,* 2006; Westly, 2008).

Effectiveness of ECT

Why is ECT considered the last resort?

Because antidepressants had not worked, the patient we just described agreed to ECT. The reason ECT is the last resort for treating depression is that ECT produces major brain seizures and may cause varying degrees of memory loss. However, even as a treatment of last resort, ECT is effective in reducing depressive symptoms in about 70–90% of patients (Husain et al., 2004). For example, the graph below shows the results for eight out of nine seriously depressed patients who had received no help from antidepressants. After a series of ECT treatments, they showed a dramatic reduction in depressive symptoms and remained symptom-free after one year (Paul et al., 1981). However, the average relapse rate after ECT treatment exceeds 50%, which means patients may need antidepressant therapy following ECT treatment or additional ECT treatments for depression (Nemeroff, 2007). Researchers are not sure how ECT works but suggest it changes brain chemistry and restores a normal balance to neurotransmitters (Salzman, 2008).



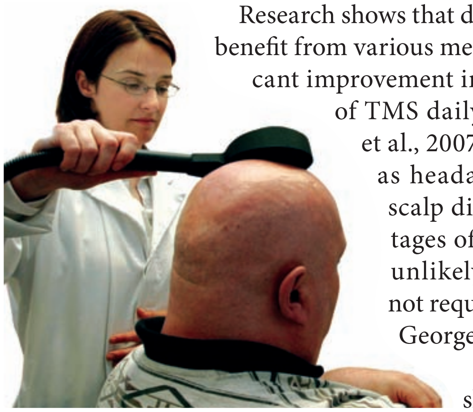
Modern ECT. Unlike patients who received ECT in the movie *One Flew Over the Cuckoo's Nest,* there is no evidence that modern ECT procedures cause brain damage or turn people into "vegetables" (Ende et al., 2000). Modifications to modern ECT, including the proper placement of electrodes on the scalp and reduced levels of electric current, have lessened the risk for complications (Nemeroff, 2007; Sackeim et al., 2000).

Memory loss. A side effect of ECT is memory loss, which ranges from a loss of memory for events experienced during the weeks of treatment to events both before and after treatment. Following ECT treatment, there is a gradual improvement in memory functions, and for most patients, memory returns to normal levels. However, some patients complain of long-term memory problems (Gitlin, 2009; Sackeim & Stern, 1997).

Mental health experts cautiously endorse ECT as a treatment of last resort for severe depression (Glass, 2001; K. G. Rasmussen, 2003). Now we'll briefly discuss another last resort treatment.

New treatment. For patients with treatment-resistant depression, a new treatment option is transcranial magnetic stimulation (shown below).

Transcranial magnetic stimulation (TMS) **is a noninvasive technique that activates neurons by sending pulses of magnetic energy into the brain.**



Research shows that depressed patients who did not benefit from various medications experienced significant improvement in symptoms after 40 minutes of TMS daily for four weeks (O'Reardon et al., 2007). Although side effects, such as headache, light-headedness, and scalp discomfort, may occur, advantages of TMS over ECT are that it is unlikely to cause seizures and does not require anesthesia (Baldauf, 2009; George, 2009).

Next, we'll discuss a disorder shared by many serial killers.

C. Personality Disorders

Definition and Types

What are serial killers like?

We have all heard the expression "Don't judge a book by its cover." That advice proved absolutely true when we heard what their friends and neighbors said about the following individuals.

His boss said David Berkowitz was "quiet and reserved and kept pretty much to himself. That's the way he was here, nice—a quiet, shy fellow." Berkowitz, known as "Son of Sam," was convicted of killing six people.

A neighbor of Westley Allan Dodd said that he "seemed so harmless, such an all-around, basic good citizen." Dodd was executed for kidnapping, raping, and murdering three small boys.

A neighbor said John Esposito "was such a quiet, caring person. He was a very nice person." Esposito was charged with kidnapping a young girl and keeping her in an underground bunker for 16 days.

Why do friends describe serial killers, such as Dahmer, as quiet, nice, and caring?

A friend said Jeffrey Dahmer "didn't have much to say, was quiet, like the average Joe." Dahmer confessed to killing and dismembering 15 people (*Time,* July 12, 1993, p. 18).

Notice how friends and neighbors judged all these cold-blooded killers to be "quiet" and "nice" and even "caring" individuals. However, while these individuals appeared very ordinary in public appearance and behavior, each was hiding a deep-seated, serious, and dangerous personality disorder (Hickey, 2006).

A ***personality disorder*** consists of inflexible, long-standing, maladaptive traits that cause significantly impaired functioning or great distress in one's personal and social life (American Psychiatric Association, 2000).

Personality disorders are found in about 9% of the adult population in the United States, affecting men and women equally, although gender may influence which personality disorder a person develops (Kluger, 2003). Of the ten different personality disorders described in DSM-IV-TR, here are seven of the more common types.

- ***Paranoid personality disorder*** is a pattern of distrust and suspiciousness and perceiving others as having evil motives (0.5–2.5% of population).
- ***Schizotypal personality disorder*** is characterized by an acute discomfort in close relationships, distortions in thinking, and eccentric behavior (3–5% of population).
- ***Histrionic personality disorder*** is characterized by excessive emotionality and attention seeking (2% of population).
- ***Obsessive-compulsive personality disorder*** is an intense interest in being orderly, achieving perfection, and having control (4% of population).
- ***Dependent personality disorder*** refers to a pattern of being submissive and clingy because of an excessive need to be taken care of (2% of population).
- ***Borderline personality disorder*** is a pattern of instability in personal relationships, self-image, and emotions, as well as impulsive behavior (2% of population).
- ***Antisocial personality disorder*** refers to a pattern of disregarding or violating the rights of others without feeling guilt or remorse (3% of population, predominantly males) (American Psychiatric Association, 2000).

Individuals with personality disorders often have the following characteristics: troubled childhoods, childhood problems that continue into adulthood, maladaptive or poor personal relationships, and abnormal behaviors that are at the extreme end of the behavioral continuum. Their difficulties arise from a combination of genetic, psychological, social, and environmental factors (Vargha-Khadem, 2000).

We'll focus on two particular personality disorders, the borderline personality and antisocial personality, because they are mentioned most often by the media.

Borderline Personality Disorder

What does it mean to be borderline?

People who have borderline personality disorder have intense, unpredictable emotional outbursts and lack impulse control, which causes them to express inappropriate anger and engage in very dangerous behaviors.

About 75% of patients with borderline personality disorder hurt themselves through cutting, burning, or other forms of self-mutilation, and another 10% eventually commit suicide. Patients with borderline personality are so emotionally erratic that they are capable of expressing profound love and intense rage almost simultaneously. Such emotional volatility makes it difficult for them to maintain stable interpersonal relationships. They are terrified of losing the people most close to them, yet they ragefully attack these same people, only to later show sweetness and affection toward them (APA, 2000; Cloud, 2009).

75% of people with borderline personality disorder hurt themselves.

We'll discuss the causes and treatment of borderline personality disorder.

Causes. Borderline personality disorder appears to have both environmental and genetic causes. Experiencing trauma during childhood, such as being abused or prohibited from expressing negative emotions, places individuals at risk for this condition. Brain scan studies have shown that the amygdala (emotional center of the brain) in these patients is overactive, while the brain areas responsible for controlling emotional responses are underactive. This helps explain why these patients lack emotional regulation. Though no specific genes have been identified, we know that the major symptoms of this condition, such as impulsivity and aggression, are highly heritable (J. E. Brody, 2009; Cloud, 2009; Meyer-Lindenberg, 2009).

Treatment. The most effective treatment for this condition is ***dialectical behavior therapy,*** a type of cognitive-behavioral therapy, which helps patients identify thoughts, beliefs, and assumptions that make their life challenging and teaches them different ways to think and react (Linehan, 1993). Typically, intense, long-term therapy is required, as well as medication.

Photo Credits: left, © Alan Fredrickson/Reuters/Corbis; right, © Angela Hampton Picture Library/Alamy

Antisocial Personality Disorder

What are people with antisocial personality disorder like?

The "nice," "quiet" killers we described would probably be diagnosed as having antisocial personality disorder or some combination of personality disorders. Between 50% and 80% of prisoners meet the criteria for a diagnosis of antisocial personality disorder (Ogloff, 2006). But, not all people diagnosed with antisocial personality disorder are alike, and the diagnostic symptoms vary along a continuum. At one end of the continuum are the chronic delinquents, bullies, and lawbreakers; at the other end are the serial killers.

Jeffrey Dahmer was diagnosed as having an antisocial personality disorder.

Delinquent. An example of someone on the delinquent end of the continuum is Tom, who always seemed to be in trouble. As a child, he would steal items (silverware) from home and sell or swap them for things he wanted. As a teenager, he skipped classes in school, set deserted buildings on fire, forged his father's name on checks, stole cars, and was finally sent to a federal institution. After Tom served his time, he continued to break the law, and by the age of 21, he had been arrested and imprisoned 50 to 60 times (Spitzer et al., 1994).

Serial killer. At the other end of the psychopathic continuum is serial killer Jeffrey Dahmer, who would pick up young gay men, bring them home, drug them, strangle them, have sex with their corpses, and then, in some cases, eat their flesh. As Dahmer said in an interview, "I could completely control a person—a person that I found physically attractive, and keep them with me as long as possible, even if it meant just keep a part of them" (Gleick et al., 1994, p. 129).

We'll discuss the causes and treatment of antisocial personality disorder.

Causes

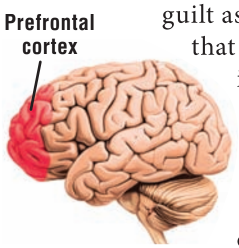
Antisocial personality disorder involves complex psychosocial and biological factors (Moffitt, 2005).

Psychosocial factors. Researchers have found that aggressive and antisocial children whom parents find almost impossible to control are at risk for developing an antisocial personality (Morey, 1997). Also, research shows that children who experience physical or sexual abuse are at an increased risk of developing antisocial personality disorder (D. Black, 2006). However, since many abused children do not develop an antisocial personality, it is difficult to determine how much childhood abuse contributes to the development of antisocial personality disorder.

Biological factors. Researchers suggest that the early appearance of serious behavioral problems, such as having temper tantrums, bullying other children, torturing animals, and habitually lying, indicates that underlying biological factors, both genetic and neurological, may predispose or place a child at risk for developing antisocial personality disorder (Pinker, 2008).

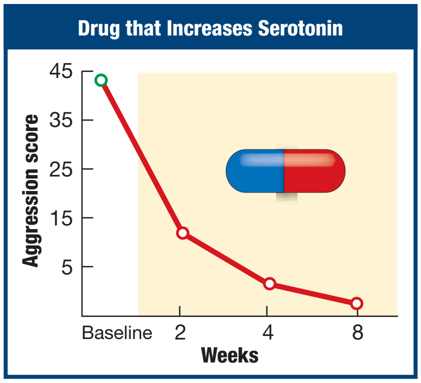
Evidence for ***genetic factors*** comes from twin and adoption studies that show that genetic factors contribute 30–50% to the development of antisocial personality disorder (Thapar & McGuffin, 1993). Evidence for ***neurological factors*** comes from individuals with brain damage and from MRI studies on the brains of individuals with antisocial personality disorder.

For example, researchers found that early brain damage to the ***prefrontal cortex*** (shown below) resulted in two children who did not learn normal social and moral behaviors and showed no empathy, remorse, or guilt as adults. In addition, MRI scans (p. 70) indicated that individuals diagnosed with antisocial personality disorder had 11% fewer brain cells in their prefrontal cortex (A. Raine et al., 2000). Since the prefrontal cortex is known to be involved in important executive functions, such as making decisions and planning, researchers suggest that damage to or maldevelopment of the prefrontal cortex predisposes or increases the risk of an individual developing antisocial personality disorder. Researchers believe that biological factors can predispose individuals to act in certain ways but that the interaction between biological and psychosocial factors results in the development and onset of personality disorders (A. B. Morgan & Lilienfeld, 2000).



Treatment

Psychotherapy has not proved very effective in treating people with antisocial personality disorder because these individuals are guiltless, mistrusting, irresponsible, and practiced liars, who fail to see that many of their behaviors are antisocial and maladaptive. As a result, psychotherapists have a very difficult time changing their behavior (Bateman & Fonagy, 2000).



Because of the relative ineffectiveness of psychotherapy, clinicians have tried various drugs that raise levels of serotonin in the brain. Researchers believe that some abnormality in the brain's serotonin system may underlie the impulsive and aggressive behaviors observed in personality disorders (D. Black, 2006). As shown in the graph above, patients who took a serotonin-increasing drug (sertraline) reported significant decreases in their aggressive behaviors across eight weeks of treatment. However, researchers caution that aggressive behaviors may return once patients stop taking these serotonin-increasing drugs (Coccaro & Kavoussi, 1997). Other research shows that the use of antipsychotic medication (p. 541) can decrease impulsivity, hostility, aggressiveness, and rage in patients with antisocial personality disorder (C. Walker et al., 2003).

Even though there are some treatment successes, researchers caution that for 69% of the patients, antisocial personality disorder is an ongoing, relatively stable, long-term problem that needs continual treatment (G. Parker, 2000).

Next, we'll examine one of the most tragic mental disorders—schizophrenia.

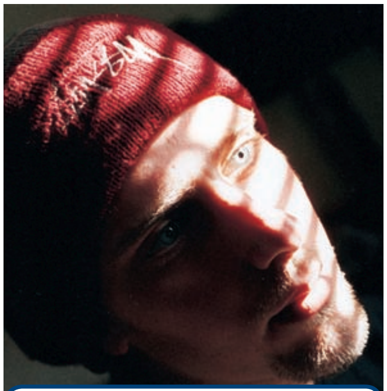
Photo Credit: top, © Alan Fredrickson/Reuters/Corbis

D. Schizophrenia

Definition and Types

What if you lose touch with reality?

At the beginning of this module, we described 18-year-old Michael McCabe (photo below), who said that his mind began to weaken during the summer of 1992. "I totally hit this point in my life where I was so high on life, it was amazing. I had this sense of independence. I was 18 and turning into an adult. Next thing I knew I got this feeling that people were trying to take things from me. Not my soul, but physical things from me. I couldn't sleep because they [his mother and sister] were planning to do something to me. I think there was a higher power inside the 7-Eleven that was helping me out the whole time, just bringing me back to a strong mental state" (C. Brooks, 1994, p. 9). Michael was diagnosed as having schizophrenia *(skit-suh-FREE-nee-ah).*



Michael McCabe had many of the symptoms described on the right.

Schizophrenia **is a serious mental disorder that lasts for at least six months and includes at least two of the following symptoms: delusions, hallucinations, disorganized speech, disorganized behavior, and decreased emotional expression. These symptoms interfere with personal or social functioning (American Psychiatric Association, 2000).**

Michael has a number of these symptoms, including delusions (higher power inside the 7-Eleven), hallucinations (hearing voices), and disorganized behavior. Schizophrenia affects about 0.2–2% of the adult population, or about 4.5 million people (equal numbers of men and women) in the United States (American Psychiatric Association, 2000).

Subcategories of Schizophrenia

Michael's case illustrates some of the symptoms that occur in schizophrenia. In fact, no two patients have exactly the same set of symptoms, which are described in the list on the right. The DSM-IV-TR describes five subcategories of schizophrenia, each of which is characterized by different symptoms. We'll briefly describe three of the more common schizophrenia subcategories.

Paranoid schizophrenia **is characterized by auditory hallucinations or delusions, such as thoughts of being persecuted by others or thoughts of grandeur.**

Disorganized schizophrenia **is marked by bizarre ideas, often about one's body (bones melting), confused speech, childish behavior (giggling for no apparent reason, making faces at people), great emotional swings (fits of laughing or crying), and often extreme neglect of personal appearance and hygiene.**

Catatonic schizophrenia **is characterized by periods of wild excitement or periods of rigid, prolonged immobility; sometimes the person assumes the same frozen posture for hours on end.**

Differentiating between types of schizophrenia can be difficult because some symptoms, such as disordered thought processes and delusions, are shared by all types.

Chances of Recovery

Chances of recovery are dependent upon a number of factors, which have been grouped under two major types of schizophrenia (Crow, 1985).

Type I schizophrenia **includes having positive symptoms, such as hallucinations and delusions, which are a distortion of normal functions. In addition, this group has no intellectual impairment, good reaction to medication, and thus a good chance of recovery.**

Type II schizophrenia **includes having negative symptoms, such as dulled emotions and little inclination to speak, which are a loss of normal functions. In addition, this group has intellectual impairment, poor reaction to medication, and thus a poor chance of recovery.**

According to this classification system, the best predictor of recovery for a person with schizophrenia is his or her symptoms: Those with positive symptoms have a good chance of recovery, while those with negative symptoms have a poor chance (Dyck et al., 2000).

Next, we'll describe the major symptoms of schizophrenia.

Symptoms

Schizophrenia is a serious mental disorder that lasts for at least six months and includes at least two of the following symptoms:

1 Disorders of thought.

These are characterized by incoherent thought patterns, formation of new words (called *neologisms*), inability to stick to one topic, and irrational beliefs or *delusions*. For example, Michael believed that his mother and sister were plotting against him.

2 Disorders of attention.

These include difficulties in concentration and in focusing on a single chain of events. For instance, one patient said that he could not concentrate on television because he couldn't watch and listen at the same time.

3 Disorders of perception.

These include strange bodily sensations and hallucinations.

Hallucinations **are sensory experiences without any stimulation from the environment.**

About 70% of schizophrenics report hearing voices that sound real and talk either to them (steal brain cells) or about them (mostly negative things, like "You have a cancer") (Thraenhardt, 2006). Research using brain imaging shows that when schizophrenics hallucinate people, their visual cortex becomes active, and when they hallucinate voices, their auditory cortex is activated (Begley, 2008c).

4 Motor disorders.

These include making strange facial expressions, being extremely active, or (the opposite) remaining immobile for long periods of time.

5 Emotional (affective) disorders.

These may include having little or no emotional responsiveness or having emotional responses that are inappropriate to the situation—for example, laughing when told of the death of a close friend.

The cause of these schizophrenia symptoms involves biological, neurological, and environmental factors.

Photo Credit: © Robert Gauthier

Biological Causes

What caused Michael's problems?

When Michael was in the hospital, his mother, Marsha (photo below), began going to a support group to get help and find out about schizophrenia. At one meeting, Marsha said, "I haven't been doing very well with this, to be perfectly honest. How in the hell were we dealt this hand?" (C. Brooks, 1994, p. 8).

Marsha tries to help her son, Michael, who has schizophrenia.

The psychiatrist who led Marsha's group answered that about 1 in 100 people get schizophrenia but the odds increase to 1 in 10 if it's already in the family. If a person inherits a predisposition for schizophrenia, any number of things—such as drugs, a death in the family, growing-up problems—can trigger its onset (C. Brooks, 1994). The psychiatrist was pointing out three major factors—biological, neurological, and environmental—that interact in the development of schizophrenia. We'll begin with biological factors, specifically genetic causes.

Genetic Predisposition

All four of these identical quadruplets developed schizophrenia.

In 1930, the birth of four identical baby girls (quadruplets) was a rare occurrence (1 in 16 million) and received great publicity. By the time the girls reached high school, all four were labeled "different." They sometimes broke light bulbs, tore buttons off their clothes, complained of bones slipping out of place, and had periods of great confusion. By young adulthood, all four girls, who are called the Genain quadruplets and share nearly 100% of their genes, were diagnosed with schizophrenia (Mirsky & Quinn, 1988). The finding that all four Genain quadruplets (above photo) developed schizophrenia indicates that increased genetic similarity is associated with increased risk for developing schizophrenia and suggests that a person inherits a ***predisposition*** for developing the disorder. Support for a genetic predisposition also comes from twin studies.

Genetic Markers

Because researchers knew that schizophrenia might have a genetic factor, they compared rates of schizophrenia in identical twins, who share nearly 100% of their genes, with rates in fraternal twins and siblings (brothers and sisters), who share only 50% of their genes. The right graph shows the risk of developing schizophrenia for individuals who share different percentages of genes and thus have different degrees of genetic similarity. Notice that if one identical twin has schizophrenia, there is a 48–83% chance that the other twin will also develop the disorder. In comparison, if one brother or sister (sibling or fraternal twin) has schizophrenia, there is only about a 10–17% chance that the other will develop the disorder (Gottesman, 2001). Because genetic factors are involved in developing schizophrenia, researchers are searching for the location of specific genes involved in schizophrenia; such genes are called genetic markers (Levinson, 2003).

A ***genetic marker*** refers to an identifiable gene or number of genes or a specific segment of a chromosome that is directly linked to some behavioral, physiological, or neurological trait or disease.

Researchers have reported many genetic markers for schizophrenia, but none proved valid because none could be repeated or replicated by other laboratories. Researchers now believe that schizophrenia depends on a combination of genes and that no one gene by itself has a strong genetic influence (ISC, 2009; T. Walsh et al., 2008).

Breakthroughs. There have been several reports of major breakthroughs in identifying genetic markers for schizophrenia. For instance, researchers found evidence of a slight excess of a protein in the prefrontal cortex of people with schizophrenia, resulting from a variation in a gene they believe may explain common symptoms of the disorder (Law & Weinberger, 2006). Also, researchers found that a disruption in a particular gene makes new neurons that are supposed to reach the hippocampus, an area of the brain important for memory and emotional processing, go elsewhere, causing a burst of abnormal brain activity, which may explain schizophrenia symptoms (H. Song, 2007). Other researchers found a gene linked to negative symptoms of schizophrenia (p. 541), which suggests that researchers should seek genes responsible for specific symptoms (Fanous et al., 2005). Taken together, recent genetic studies plus earlier studies on identical twins indicate that schizophrenia has a genetic factor.

Infections

Another biological factor that may contribute to the development of schizophrenia is infections. For instance, pregnant women who get the flu have been found to be more likely to give birth to children who will develop schizophrenia. Also, some childhood infections, such as the mumps virus, have been associated with an increased risk of later developing schizophrenia symptoms. Researchers believe that some infections directly affect the brain, whereas others trigger immune reactions that interfere with normal brain development (Dalman et al., 2008; Wenner, 2008a).

However, biological factors alone cannot completely explain why individuals develop schizophrenia. As we'll discuss, environmental factors must interact with biological factors (Mueser et al., 2006).

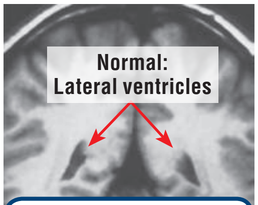
D. Schizophrenia

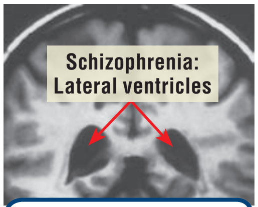
Neurological Causes

Is the brain different?

New techniques for studying the structures and functions of the living brain (MRI and fMRI—p. 70) reveal major differences between brains of schizophrenics and brains of mentally healthy individuals. We'll discuss two reliable differences—larger ventricles and decreased activity in the prefrontal cortex.



Fluid-filled ventricles in normal brains



Increased size of fluid-filled ventricles in brains of schizophrenics

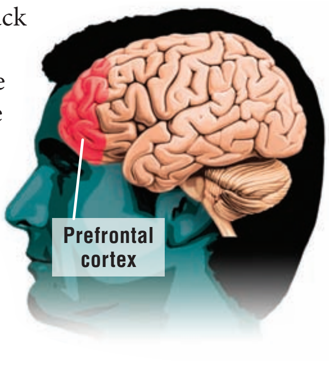
Ventricle Size

Most us of don't realize that our brains have four fluid-filled cavities called ventricles (left figure). The fluid in these cavities helps to cushion the brain against blows and also serves as a reservoir of nutrients and hormones for the brain. One reliable finding is that in up to 80% of the brains of schizophrenics, the ventricles are larger than normal (Niznikiewicz et al., 2003). Using brain scans (MRIs), researchers studied 15 pairs of identical twins; one was diagnosed with schizophrenia, while the other was mentally healthy (normal). The brains of twins with schizophrenia had ***larger ventricles*** than the brains of the mentally healthy twins (left figures) (Suddath et al., 1990). However, not all brains of people with schizophrenia have larger ventricles or an overall decrease in brain size. Also, the enlarged ventricles in some schizophrenics may remain the same over the course of their illness, while the size of ventricles may change over time for others (DeLisi et al., 2004). Researchers conclude that some people with schizophrenia have abnormally large ventricles, which results in a reduction in brain size and in turn may contribute to the development of schizophrenia (I. C. Wright et al., 2000).

Frontal Lobe: Prefrontal Cortex

Another brain structure involved in many executive functions, such as reasoning, planning, remembering, paying attention, and making decisions, is the prefrontal cortex (figure below). Researchers report that in pairs of identical twins where one twin has schizophrenia and the other does not, the brain of the twin with schizophrenia was characterized by significantly ***less activation of the prefrontal cortex*** (F. E. Torrey et al., 1994). This decreased prefrontal lobe activity is consistent with the deficits in many executive functions observed in schizophrenics, such as disorganized thinking, irrational beliefs, and lack of concentration (Niznikiewicz et al., 2003).

Other researchers report that in the brains of people with schizophrenia, the frontal and temporal lobes are smaller because there are fewer brain cells (neurons—p. 50) and fewer connections (axons—p. 50) among neurons (K. Davis, 2003; Pantelis et al., 2003). Fewer neurons with fewer connections cause deficits in transmitting information, which in turn may underlie problems in executive functions, such as disorganized thinking and reasoning, which are major symptoms of patients diagnosed with schizophrenia (Holden, 2003).



These studies point to neurological factors, such as abnormal brain structures and functions, that researchers believe underlie and contribute to the development of schizophrenia and make it so difficult to treat (Holden, 2003).

Besides genetic and neurological factors, there are also environmental factors involved in developing schizophrenia.

Environmental Causes

Can stress act as a trigger?

If biological or neurological factors explained why people develop schizophrenia, then the risk for developing schizophrenia in identical twins would be almost 100% rather than 48–83%. Because biological and neurological factors alone cannot explain the development of schizophrenia, researchers look at the influence of environmental factors, such as the incidence of stressful events and how individuals cope. For example, when Michael McCabe (right photo) was 18, he began to develop symptoms of schizophrenia. The onset of these symptoms occurred after the death of his father and during the potentially stressful period of adolescence.

Stressful events may have led to his onset of schizophrenia.

Stressful events, such as hostile parents, poor social relationships, the death of a parent or loved one, and career or personal problems, can contribute to the development and onset of schizophrenia. This relationship between stress and the onset of schizophrenia is called the diathesis stress theory (S. R. Jones & Fernyhough, 2007).

The ***diathesis*** *(die-ATH-uh-sis)* ***stress theory*** of schizophrenia says that some people have a genetic predisposition (a diathesis) that interacts with life stressors to result in the onset and development of schizophrenia.

The diathesis stress theory assumes that biological or neurological factors have initially produced a ***predisposition for schizophrenia.*** If a person already has a predisposition for schizophrenia, then being faced with stressful environmental factors can increase the risk and vulnerability for developing schizophrenia as well as trigger the onset of schizophrenia symptoms (S. R. Jones & Fernyhough, 2007). Thus, the diathesis stress theory says that biological and neurological factors first create a predisposition, such as overreacting to stressful situations, that then makes a person vulnerable or at risk for developing schizophrenia.

Now we'll examine the drugs used to treat schizophrenia.

Treatment

How is Michael treated?

After Michael (right photo) was taken to the psychiatric hospital, his symptoms were assessed and he was diagnosed with schizophrenia. Schizophrenia symptoms are commonly divided into positive and negative symptoms.

Positive symptoms of schizophrenia reflect a distortion of normal functions: distorted thinking results in delusions; distorted perceptions result in hallucinations; and distorted language results in disorganized speech.

Negative symptoms of schizophrenia reflect a decrease in or loss of normal functions: decreased range and intensity of emotions, decreased ability to express thoughts, and decreased initiative to engage in goal-directed behaviors (American Psychiatric Association, 2000).

Michael was given a neuroleptic drug to treat his schizophrenia.

Like most individuals diagnosed with schizophrenia, Michael had both positive symptoms, such as delusions that people were going to steal from him, and negative symptoms, such as loss of emotional expression. To reduce these symptoms, he was given haloperidol, which is an example of an antipsychotic or neuroleptic (meaning "taking hold of the nerves") drug.

Neuroleptic drugs, also called ***antipsychotic drugs,*** are used to treat serious mental disorders, such as schizophrenia, by changing the levels of neurotransmitters in the brain.

There are two kinds of neuroleptic drugs: typical and atypical.

Typical Neuroleptics

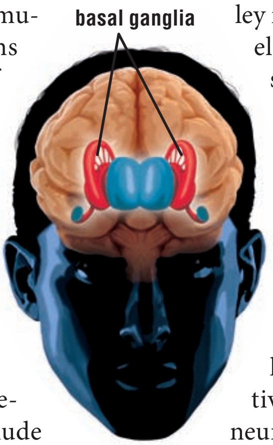
Typical neuroleptics: decrease dopamine

Typical neuroleptics were discovered in the 1950s and were the first effective medical treatment for schizophrenia.

Typical neuroleptic drugs primarily reduce levels of the neurotransmitter dopamine. These drugs mainly reduce positive symptoms and have little effect on negative symptoms. Because typical neuroleptics reduce levels of dopamine, their action supports the dopamine theory of schizophrenia (Downar & Kapur, 2008).

The ***dopamine theory*** says that in schizophrenia, the dopamine neurotransmitter system is somehow overactive and gives rise to a wide range of symptoms.

The dopamine theory focuses on neurons in a group of brain structures called the ***basal ganglia*** (figure below). Typical neuroleptics block dopamine usage in the basal ganglia, which reduces communication among these neurons and in turn reduces some of the symptoms of schizophrenia. However, because 20% of people with schizophrenia are not helped by typical neuroleptics and because recent findings point to the involvement of several nondopamine neurotransmitters (serotonin and glutamate), the dopamine theory will need revision to include other neurotransmitter systems.



Using typical neuroleptics to treat schizophrenia is being challenged by newer drugs, called atypical neuroleptics.

Atypical Neuroleptics

Atypical neuroleptics: decrease dopamine & serotonin

In Michael's case and for about 20% of all schizophrenics, typical neuroleptic drugs (phenothiazines, such as haloperidol or Thorazine) have little or no effect on their symptoms. Many of these patients are being helped by newer atypical neuroleptic drugs.

Atypical neuroleptic drugs (clozapine, risperidone) lower levels of dopamine and also lower levels of other neurotransmitters, especially serotonin. These drugs primarily reduce positive symptoms, may reduce negative symptoms, and prevent relapse (Downar & Kapur, 2008).

The first atypical neuroleptic, clozapine, was approved for use in schizophrenia in 1990. Since then, atypical neuroleptics have proven effective in decreasing symptoms of schizophrenia, especially in patients who were not helped by typical neuroleptics (W. Carpenter, 2003).

Michael, for example, showed little improvement with typical neuroleptics (haloperidol). However, the atypical neuroleptic clozapine reduced his positive symptoms to the point that he was allowed to leave the psychiatric hospital and return home. A year later, Michael was still taking clozapine and was making slow progress in overcoming his symptoms, such as paranoia.

On most days, Michael comes home from group therapy and job-training classes, puts on a Bob Marley record, and sits and listens, afraid to do much else. As Michael explains, "I can't go out and skate or do anything because I'm afraid I'm going to have a paranoia attack" (C. Brooks, 1995b, p. D-3). His mother and sister provide Michael with financial and social support but wish Michael would take greater initiative to improve his own life. Michael, as well as others with schizophrenia, face a daily struggle to overcome their symptoms, which points to the need for continued social support and psychotherapy (Bustillo et al., 2001).

Atypical neuroleptics helped Michael (shown with his mother and sister) reduce his symptoms.

Current treatment. For many years, compared to typical neuroleptics, atypical neuroleptics were the preferred treatment because they were reported to be at least as effective in reducing positive symptoms, more effective in reducing negative symptoms, and helpful for patients who showed no improvement with typical neuroleptics (S. Burton, 2006; J. M. Davis et al., 2003). More recently, a large, carefully conducted study compared the cognitive effects of the two types of neuroleptics and found that, contrary to previous research outcomes, typical and atypical neuroleptics were about equally effective in boosting cognitive skills (R. S. E. Keefe et al., 2007).

Next, we'll discuss the serious side effects of typical and atypical neuroleptics.

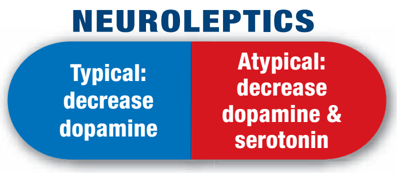
D. Schizophrenia

Evaluation of Neuroleptic Drugs

What are the side effects?

The major advantage of neuroleptic drugs is that they effectively reduce positive symptoms so that many patients can regain some degree of normal functioning. However, neuroleptics also have two potentially serious disadvantages: They may produce undesirable side effects, and they may decrease but not prevent relapse or return of the original symptoms of schizophrenia.



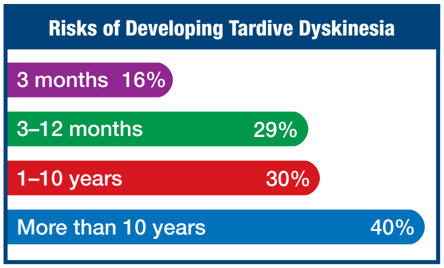
NEUROLEPTICS
Typical: decrease dopamine
Atypical: decrease dopamine & serotonin

Typical Neuroleptics

Side effects. One group of typical neuroleptics, called the phenothiazines *(pheen-no-THIGH-ah-zeens),* is widely prescribed to treat schizophrenia. Phenothiazines can produce unwanted motor movements, which is a side effect called tardive dyskinesia (Dolder, 2008).

Tardive dyskinesia *(TAR-div dis-cah-KNEE-zee-ah)* involves the appearance of slow, involuntary, and uncontrollable rhythmic movements and rapid twitching of the mouth and lips, as well as unusual movements of the limbs. This condition is associated with the continued use of typical neuroleptics.

As shown in the right graph, the risk for developing tardive dyskinesia increases with use: After three months, 16% developed this side effect; after ten years, 40% developed it (Sweet et al., 1995). About 30% of patients with tardive dyskinesia will experience a reduction in symptoms if they are taken off typical neuroleptics, but the remaining 70% may continue to have the problem when the drug therapy is stopped (Roy-Byrne & Fann, 1997).



Effectiveness. Researchers have completed several long-term follow-up studies on patients who were treated for schizophrenia with typical neuroleptics. They found that, 2 to 12 years after treatment, about 20–30% of patients showed a good outcome, which means they needed no further treatment and had no relapse; about 40–60% continued to suffer some behavior impairment and relapse, although their symptoms reached a plateau in about 5 years and did not worsen after that; and about 20% were not helped by these drugs.

Unwanted motor movements (lip smacking) are a side effect of typical neuroleptics but less so with atypical neuroleptics.

Relapse. The basic problem with taking patients off typical neuroleptics is that they may relapse. For example, after an average of about one year, 60% of patients taken off a typical neuroleptic experienced a relapse, as compared to a relapse rate of 34% for those who were maintained on an atypical neuroleptic (Csernansky et al., 2002).

Next, we'll learn about the side effects and effectiveness of the newer atypical neuroleptics.

Atypical Neuroleptics

Side effects. One advantage of atypical neuroleptics is they cause tardive dyskinesia in only about 5% of patients, compared to 1–29% of patients given typical neuroleptics (Caroff et al., 2002). However, atypical neuroleptics can cause side effects, the most serious being increased levels of cholesterol and glucose or blood sugar, weight gain, and onset or worsening of diabetes (S. Burton, 2006; Dolder, 2008). Thus, typical and atypical neuroleptics may produce serious side effects.

Effectiveness and relapse. From the 1950s through the middle of the 1990s, the drugs of choice for treating schizophrenia were typical neuroleptics. Beginning in the late 1990s and continuing to the present, there has been a general switch to atypical neuroleptics. That's because, compared to typical neuroleptics, atypical neuroleptics have generally proved to be as effective in reducing positive symptoms, more effective in reducing negative symptoms, less likely to cause tardive dyskinesia, and more effective in preventing relapse, the recurrence of schizophrenia symptoms (S. Burton, 2006; J. M. Davis et al., 2003). However, some research found that the use of typical and atypical drugs led to about equal improvement in patients with schizophrenia and similar rates of movement-related side effects, such as tardive dyskinesia (J. A. Lieberman, 2005). Due to these inconsistencies, clinicians must carefully consider which type of drug to prescribe to their patients.

Conclusions. Two strange, recurring findings in the treatment of mental disorders are that the same drug may help one patient but not another, and for some patients drugs cause no improvement at all. One reason drugs don't always work is that mental disorders, like schizophrenia, may have different causes (genetic, neurological, environmental) that may require a combination of different drugs and/or psychotherapy. Another reason drugs don't always work is that each person's nervous system functions differently and has a different level of neurotransmitters (Niznikiewicz et al., 2003). This explains why the same drug may cause various types and severities of side effects for different people.

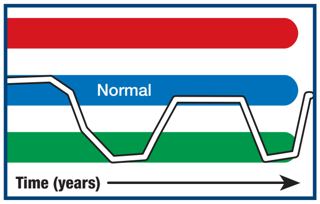
Researchers find that, for the majority of patients, schizophrenia is a chronic or life-long problem with a high risk for relapse. Thus, in addition to drug treatment, patients need psychotherapy and social support to improve their social interactions, work at an acceptable job, and maintain their quality of life (Lauriello, 2007; Mueser et al., 2006).

New direction. Because some patients with schizophrenia either do not benefit from typical or atypical neuroleptics or experience intolerable side effects, researchers have been working to create a new drug that targets a different neurotransmitter called glutamate. Glutamate may be just as important as dopamine and serotonin in schizophrenia because it is associated with perception, memory, emotion, and concentration. Scientists think drugs that target glutamate will provide patients with another treatment option that promises to be effective and have limited side effects (Berenson, 2008; Downar & Kapur, 2008; Goff, 2008; S. F. Locke, 2008).

After the Concept Review, we'll discuss a disorder that has a very strange symptom—the person does not know who he or she is.

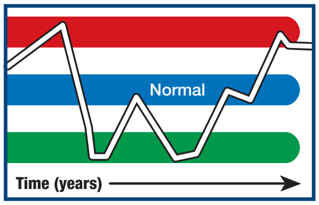
Concept Review

1. A prolonged emotional state that affects almost all of a person's thoughts and behaviors is called a ________ disorder.



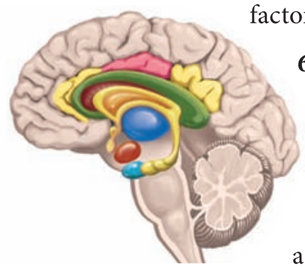
2. The most common form of mood disorder is marked by at least two weeks of daily being in a bad mood, having no interest in anything, and getting no pleasure from activities and having at least four of these additional symptoms: problems with weight or appetite, insomnia, fatigue, difficulty thinking, and feeling worthless and guilty. This problem is called ________ disorder.

3. Another depressive disorder is characterized by being chronically depressed for many but not all days over a period of two years and having two of the following symptoms: poor appetite, insomnia, fatigue, low self-esteem, and feelings of hopelessness. This problem is called ________ disorder.

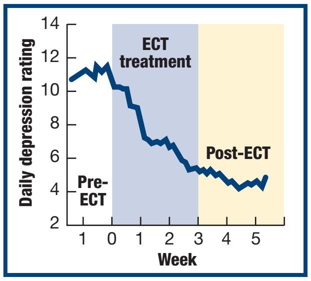


4. Another mood disorder is characterized by a fluctuation between a depressive episode and a manic episode that lasts about a week, during which a person is unusually euphoric, cheerful, or high, speaks rapidly, feels great self-esteem, and needs little sleep. This problem is called ________ disorder.

5. Underlying genetic, neurological, chemical, or physiological components may predispose a person to developing a mood disorder. Together, these components are called ________ factors.



6. Factors such as dealing with stressors and stressful life events are believed to interact with predisposing biological factors and contribute to the development, onset, and maintenance of mood disorders. These are called ________ factors.



7. One treatment for major depression involves placing electrodes on the skull and administering a mild electric current that passes through the brain and causes a seizure. Usual treatment consists of a series of 10 to 12 such sessions, at the rate of about three per week. This treatment is called ________.

8. Certain psychoactive drugs act by increasing levels of a specific group of neurotransmitters (monoamines, such as serotonin) that are believed to be involved in the regulation of emotions and moods. These are called (a) ________ drugs. A mood stabilizer that is used to treat bipolar I disorder is called (b) ________, and it's often combined with antidepressants and antipsychotics.

9. A person who has inflexible, long-standing, maladaptive traits that cause significantly impaired functioning or great distress in his or her personal and social life is said to have a (a) ________ disorder. Examples of this disorder include a pattern of distrust and suspiciousness and perceiving others as having evil motives, which is called a (b) ________ personality disorder; a pattern of being submissive and clingy because of an excessive need to be taken care of, which is called a (c) ________ personality disorder; and a pattern of disregarding or violating the rights of others without feeling guilt or remorse, which is called an (d) ________ personality disorder.

10. A serious mental disturbance that lasts for at least six months and that includes at least two of the following persistent symptoms—delusions, hallucinations, disorganized speech, grossly disorganized behavior, and decreased emotional expression—is called (a) ________. There are subcategories of this disorder: the one characterized by auditory hallucinations or delusions, such as thoughts of being persecuted by others or thoughts of grandeur, is called (b) ________ schizophrenia.

________:
decrease dopamine
________:
decrease dopamine & serotonin

11. Drugs that are used to treat schizophrenia and act primarily to reduce levels of dopamine are called (a) ________ drugs. Drugs that are used to treat schizophrenia and reduce levels of dopamine and levels of serotonin are called (b) ________ drugs, which are generally more effective than (c) ________ drugs. The theory that, in schizophrenia, the dopamine neurotransmitter system is somehow overactive and gives rise to many of the symptoms observed in schizophrenics is called the (d) ________ theory, which is supported by the actions of (e) ________ drugs but not by the actions of (f) ________ drugs.

Answers: *1. mood; 2. major depressive; 3. dysthymic; 4. bipolar I; 5. biological; 6. psychosocial; 7. electroconvulsive therapy, or ECT; 8. (a) antidepressant, (b) lithium; 9. (a) personality, (b) paranoid, (c) dependent, (d) antisocial; 10. (a) schizophrenia, (b) paranoid; 11. (a) typical neuroleptic, (b) atypical neuroleptic, (c) typical neuroleptic, (d) dopamine, (e) typical neuroleptic, (f) atypical neuroleptic*

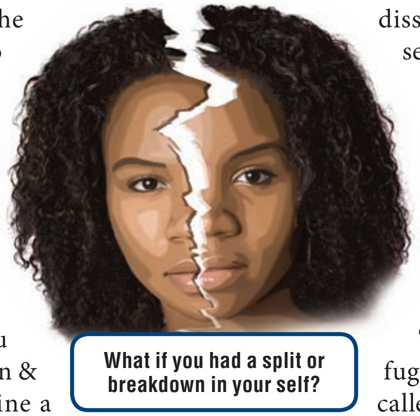
E. Dissociative Disorders

Definition

What if you became someone else?



What if you had a split or breakdown in your self?

You have probably had the experience of being so absorbed in a fantasy, thought, or memory that, for a short period of time, you cut yourself off from the real world. However, if someone calls your name, you quickly return and explain, "I'm sorry, I wasn't paying attention. I was off in my own world." This is an example of a normal "break from reality," or dissociative experience, which may occur when you are self-absorbed, hypnotized, or fantasizing (Berlin & Koch, 2009; Kihlstrom et al., 1994). Now imagine a dissociative experience so extreme that your own self splits, breaks down, or disappears.

A *dissociative disorder* is characterized by a person having a disruption, split, or breakdown in his or her normal integrated self, consciousness, memory, or sense of identity. This disorder is relatively rare and unusual (American Psychiatric Association, 2000).

We'll discuss three of the five more common dissociative disorders listed in the DSM-IV-TR. These are dissociative amnesia, dissociative fugue, and dissociative identity disorder (formerly called multiple personality disorder).

Dissociative Amnesia

Mark is brought into the hospital emergency room by police. He looks exhausted and is badly sunburned. When questioned, he gives the wrong date, answering September 27th instead of October 1st. He has trouble answering specific questions about what happened to him. With much probing, he gradually remembers going sailing with friends on about September 25th and hitting bad weather. He cannot recall anything else; he doesn't know what happened to his friends or the sailboat, how he got to shore, where he has been, or where he is now. Each time he is told that it is really October 1st and he is in a hospital, he looks very surprised (Spitzer et al., 1994). Mark is suffering from dissociative amnesia.

I can't remember anything about the past month.

Dissociative amnesia is characterized by the inability to recall important personal information or events and is usually associated with stressful or traumatic events. The importance or extent of the information forgotten is too great to be explained by normal forgetfulness (American Psychiatric Association, 2000).

In Mark's case, you might think his forgetfulness was due to a blow to the head suffered on the sailboat in rough seas. However, doctors found no evidence of head injury or neural problems. To recall the events between September 25th and October 1st, Mark was given a drug (sodium amytal) that helps people relax and recall events that may be blocked by stressful experiences. While under the effect of the drug, Mark recalled a big storm that washed his companions overboard but spared him because he had tied himself to the boat. Thus, Mark did suffer from dissociative amnesia, which was triggered by the stressful event of seeing his friends washed overboard (Spitzer et al., 1994). In dissociative amnesia, the length of memory loss varies from days to weeks to years and is often associated with a series of stressful events (Eich et al., 1997).

As we'll see next, a person may even forget who he or she is.

Dissociative Fugue

A 40-year-old man wanders the streets of Denver with $8 in his pocket. He asks people to help him figure out who he is and where he lives. He feels lost, alone, anxious, and desperate to learn his identity. He appears on news shows pleading for help: "If anybody recognizes me, knows who I am, please let somebody know" (Ingram, 2006). After his parents and fiancée see him on television, they contact the police, informing them that the man's name is Jeffrey Ingram and that he lives in Seattle. Upon reuniting with his fiancée and family, Jeffrey fails to recognize their faces. He also cannot recall anything about his past (Woodward, 2006). Jeffrey Ingram had experienced dissociative fugue.

Who am I?
What's my name?

Dissociative fugue is a disturbance marked by suddenly and unexpectedly traveling away from one's home or place of work and being unable to recall one's past. The person may not remember his or her identity or may be confused about his or her new assumed identity (American Psychiatric Association, 2000).

Before clinicians diagnosed Jeffrey as suffering from dissociative fugue, they ruled out drugs, medications, and head injuries. His fiancée explained that Jeffrey had been on his way to Canada to visit his friend's wife, who was dying of cancer. She believes the stress of seeing his friend's wife dying led him to an amnesia state. Jeffrey's history is especially fascinating because he had experienced a similar dissociative fugue in 1995, when he disappeared during a trip to the grocery store and wasn't found until 9 months later. And, Jeffrey recently went missing for a third time! This time, he was quickly identified because he had gotten a tattoo on his arm that gave his name and state ID number. Jeffrey is now considering his options to always have GPS technology with him so his family can quickly find him if he should go missing again (Alexander, 2007).

As Jeffrey's case illustrates, the onset of dissociative fugue is related to stressful life events. Usually, fugue states end quite suddenly, and the individual recalls most or all of his or her identity and past.

In other cases, a person's self splits into two or more "true" selves or identities, which is called dissociative identity disorder.

Photo Credit: right, © AP Images/*The Denver Post*/Karl Gehring

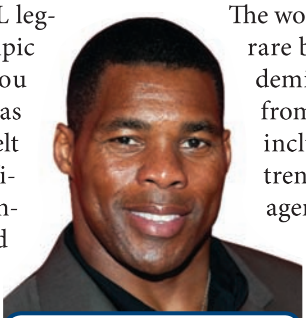
Dissociative Identity Disorder

Is it really true?

The idea that one individual could possess two or more "different persons" who may or may not know one another and who may appear at different times to say and do different things describes one of the more remarkable and controversial mental disorders (Eich et al., 1997). Previously this disorder was called multiple personality disorder, but now it's called dissociative identity disorder. We'll discuss a real case of dissociative identity disorder and its possible causes.

Definition

Herschel Walker is recognized for being an NFL legend, Heisman Trophy winner, track star, Olympic competitor, and successful businessman. You would think Herschel would feel as though he was on top of the world. On the contrary, Herschel felt that his life was out of his control. He had difficulty managing his anger, he struggled to feel connected to people, and he experienced unexplained periods of memory loss.



Football legend Herschel Walker is diagnosed with dissociative identity disorder, formerly called multiple personality disorder.

Herschel's wife of 16 years (now divorced) also noticed several oddities about him. For instance, she described him as having many different sides, such as the side with an interest in the Marines, the side interested in ballet, the side interested in the FBI, and the side interested in sports. She even noticed that he would occasionally speak in different voices and show uniquely different physical mannerisms.

After Herschel got the courage to seek professional help to understand what had been happening to him, his therapist diagnosed him as suffering from a very rare and complex disorder called dissociative identity disorder.

Dissociative identity disorder (formerly called multiple personality disorder) is the presence of two or more distinct identities or personality states, each with its own pattern of perceiving, thinking about, and relating to the world. Different personality states may take control of the individual's thoughts and behaviors at different times (American Psychiatric Association, 2000).

As a boy, Herschel was severely teased and bullied for being an overweight child who had a severe stutter. His therapist explains that Herschel developed his alter personalities to help him overcome the abuse by his peers as well as other major challenges he faced later in life.

Herschel identifies about a dozen alter personalities, including "The Hero," who came out in public appearances, and "The Warrior," who was in charge of playing football and coping with the physical pain that came with it. Herschel's therapist describes meeting the alter personalities in therapy by saying, "They will come out and say, I am so-and-so. I'm here to tell you Herschel is not doing too good.... When he finishes, it would just disappear back in him, and Herschel comes out" (Mungadze, 2008).

As in Herschel's case, the personalities are usually quite different and complex, and the original personality is seldom aware of the others. After nearly ten years of psychotherapy, Herschel managed to obtain great insight about his condition and says he is doing much better now (H. Walker, 2008; Woodruff et al., 2008).

How common is dissociative identity disorder, and what causes it?

Occurrence and Causes

The worldwide occurrence of dissociative identity disorder was very rare before 1970, with only 36 cases reported. However, an "epidemic" occurred in the 1970s and 1980s, with estimates ranging from 300 to 2,000 cases (Spanos, 1994). Reasons for the upsurge include incorrect diagnosis, renewed professional interest, the trendiness of the disorder, and therapists' (unknowing) encouragement of patients to play the roles. Whatever the reasons, the vast majority (70–80%) of mental health professionals are skeptical about the upsurge in occurrence of dissociative identity disorder (Lilienfeld et al., 1999). The patients most often diagnosed with dissociative identity disorder (DID) are females, who outnumber males by 8 to 1. In addition, patients with DID usually have a history of other mental disorders.

Explanations. There are two opposing explanations for DID. One is that DID results from the severe trauma of childhood abuse, which causes a mental splitting or dissociation of identities as one way to defend against or cope with the terrible trauma. A second explanation is that DID has become commonplace because of cultural factors, such as DID becoming a legitimate way for people to express their frustrations or to manipulate or gain personal rewards (Lilienfeld et al., 1999). These opposing explanations reflect the current controversy about why so many patients have been diagnosed with DID.

Dissociative identity disorder is said to have two very different causes.

Researchers have found biological evidence to support the existence of dissociative identity disorder. For instance, they found that the brains of patients with the condition generate multiple distinct patterns of seeing, thinking, and behaving. Their physiological arousal patterns (e.g., heartbeat, brain wave activity) are distinctively different depending on which alter is present (Reinders et al., 2006).

Treatment. Patients diagnosed with DID may also have problems with depression, anxiety, interpersonal relationships, and substance abuse. As a result, treatment for DID involves helping patients with these related problems as well as helping them integrate their various personalities into one unified self, which may take years. For example, after two years of treatment, patients diagnosed with DID who showed the greatest improvement were those who showed the greatest ability to integrate and resolve the differences of their separate selves and see themselves as a person with a single self. Clinicians concluded that treatment for DID is a long-term process that usually involves some form of psychotherapy (Chu et al., 2005).

F. Cultural Diversity: Interpreting Symptoms

Spirit Possession

How does the world view mental disorders?

Imagine being a clinician and interviewing a 26-year-old female client who reports the following symptoms: "Sometimes a spirit takes complete control of my body and mind and makes me do things and say things that I don't always remember. The spirit is very powerful and I never know when it will take control. The spirit first appeared when I was 16 and has been with me ever since."

As a clinician, you would of course conduct a much more in-depth clinical interview and administer a number of psychological tests. But on the basis of these symptoms alone, would you say that she has delusions and hallucinations and possibly schizophrenia or that she has multiple identities and possibly dissociative identity disorder? In this case, both diagnoses would be incorrect. This female client comes from a small village in Northern Sudan, where spirit possession is part of their culture and about 45% of married women over 15 years of age report spirit possession (Boddy, 1988). Although in the United States symptoms of spirit possession would probably be interpreted as delusional and abnormal, in Northern Sudan spirit possession is interpreted as a normal behavior and an expression of the women's culture. To deal with possible cultural differences, the DSM-IV-TR now includes an appendix that describes how to diagnose symptoms within the context of a person's culture (American Psychiatric Association, 2000).

About 45% of the women in Northern Sudan report spirit possession, which is part of their culture.

Spirit possession is an example of how cultural factors determine whether symptoms are interpreted as normal or abnormal. Researchers are also finding that cultural factors and gender influence the occurrence of certain other kinds of mental disorders. We'll examine how culture and gender influence the occurrence of mental disorders.

Culture-Specific Mental Disorders

Mental illness is present across all cultures; however, cultures often differ in what they consider to be normal and abnormal. There are some mental disorders that are unique to a culture and are best understood within the context of a particular culture. They are collectively referred to as culture-specific disorders.

A ***culture-specific disorder*** is a pattern of mental illness or abnormal behavior that is unique to an ethnic or cultural population and does not match the Western classifications of mental disorders (APA, 2007).

Cross-cultural research has identified numerous culture-specific disorders, a few of which are described below (Gaw, 2001).

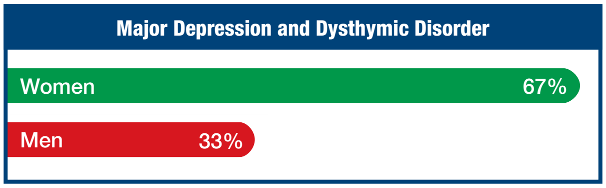
Some mental disorders are unique to specific ethnic or cultural populations.

- ***Latah*** involves the inability to stop copying or imitating others' behaviors, such as movements and speech. Individuals with this disorder are susceptible to doing things they wouldn't typically do, such as using intense profanity. Latah is found in Malaysian and Indonesian cultures.
- ***Bibloqtoq*** involves an intense urge to leave one's home, tear off one's clothes, and expose oneself to the freezing cold weather. It is found in Greenland, Alaska, and the Canadian Arctic.
- ***Susto*** involves insomnia, depression, and anxiety and is often brought on by fear. It is found among the people of the Andean highlands and is believed to develop from contact with witches and the evil eye.
- ***Koro*** involves the fear and sensation of one's penis retracting into the body and the belief that one will die as a result. This syndrome is found in Malaysian cultures.

These examples show the importance of cultural factors in mental disorders. Cultural factors influence not only the occurrence of disorders but also the rates of occurrence in males and females.

Gender Differences in Mental Disorders

Many mental disorders in the United States, such as bipolar I disorder and personality disorders, are reported about equally by women and men (Kluger, 2003; C. F. Newman, 2006). However, as shown in the graph below, disorders such as major depression and dysthymic disorders are reported significantly more frequently by women than by men in the United States as well as in many other countries around the world (Kessler, 2003; Thase, 2006).



Some clinicians attribute the higher percentage of women reporting depression to cultural differences in gender roles. For example, the stereotypical gender role for men is to be independent and assertive and to take control, which tends to reduce levels of stress. In comparison, the stereotypical gender role for women is to be dependent, passive, and emotionally sensitive, which reinforces women's feelings of being dependent, not having control, and being helpless, and increases levels of stress and puts women at greater risk for developing depression (Durand & Barlow, 2006). Some researchers suggest that biological (hormonal changes) and psychosocial (concerns over having and raising children) factors may also contribute to women's higher rate of depression (NIMH, 2005).

Compared with men, twice as many women report problems with depression.

Next, we'll look at a very simple yet effective treatment for depression.

G. Research Focus: Exercise Versus Drugs

Choices of Therapy for Depression

Can exercise help?

What would you think if you were in the middle of feeling very depressed and someone recommended running three times a week as a good treatment? It seems hard to believe that something as simple as exercising could be as effective as antidepressants. Remember that major depression is not how you feel from having a bad day or doing poorly on an exam. Major depression must meet the following definition.

Major depressive disorder is marked by at least two weeks of continually being in a bad mood, having no interest in anything, and getting no pleasure from activities. In addition, a person must have at least four of the following symptoms: problems with eating, sleeping, thinking, concentrating, or making decisions, lacking energy, thinking about suicide, and feeling worthless or guilty (American Psychiatric Association, 2000).

Can depressed people get help from walking?

We have already discussed how psychotherapy, antidepressants, and a combination of the two have proven effective in treating major depression (Goode, 2003). Now researchers are asking if regular exercise can also be effective in treating major depression.

This Research Focus shows how scientists used the experimental approach to answer a question that potentially has very practical or applied benefits.

Exercise Experiment: Seven Rules

Method and Results

You may remember that there are seven rules for doing an experiment (pp. 36–37). We'll review these seven rules by showing how researchers followed them in their study (Babyak et al., 2000).

Rule 1: Ask. Every experiment asks a specific question that is changed into a hypothesis or educated guess. In this study, the ***hypothesis*** is that exercise will be as effective a treatment for major depression as are antidepressants.

Antidepressants: independent variable

Exercise: independent variable

Rule 2: Identify. Researchers ***identify*** the treatment, which is called the ***independent variable*** because researchers are able to control or administer it to the subjects. Here, the independent variable has three levels of treatments: the first level is 30 minutes of exercise (stationary bike or walking/jogging) three times a week; the second level is taking antidepressants (Zoloft); and the third level is a combination of exercising and taking antidepressants.

Scale to measure depression: dependent variable

Next, researchers ***identify*** the behavior(s), called the ***dependent variable,*** which depends on the treatment, and measure its effectiveness. In this study, the dependent variable is a scale (Hamilton rating scale for depression) that measures increases or decreases in subjects' depression.

Rule 3: Choose. Researchers ***choose*** subjects, who in this study are 156 adult volunteers (50 years or older) who have been diagnosed with major depression (according to the above definition).

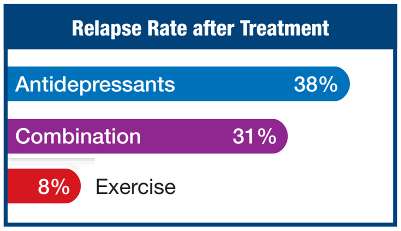
Rule 4: Assign. The chosen patients are ***randomly assigned*** to groups, which means that each of the 156 patients has an equal chance of being assigned to one of the three treatment groups.

Rule 5: Manipulate. Researchers administer or ***manipulate*** the three levels of the treatment by giving one level of treatment to each of the three groups of patients.

Rule 6: Measure. After 4 months of treatments, researchers use the depression scale to ***measure*** how effective each one of the three levels of treatment was in decreasing the patients' depression.

Rule 7: Analyze. Researchers found that about 60% of patients in the exercise group had greatly improved, compared with 66% of subjects taking antidepressants and 69% of those who combined exercise and antidepressants. Although these percentages look different, ***statistical analysis*** indicated that the three treatments were equally effective. This means that exercise alone was as effective in reducing depression as were antidepressants or the combination, which supports the researchers' original hypothesis.

Relapse



We discussed how, after treatment for a mental disorder, a certain percentage of patients relapse or again return to having symptoms. Of the 60–69% of patients in each of the three treatment groups who showed significant improvement (few if any depressive symptoms), some patients had relapsed during the 6-month period following treatment. Researchers reported (above graph) that 38% of patients who had received antidepressants had relapsed and 31% of patients who had received both exercise and antidepressants had relapsed. However, only 8% of patients relapsed who were in the exercise-only treatment.

Conclusions

Researchers found that after 4 months of treatment for depression, patients in all three treatment groups showed improvement. However, when patients were retested 6 months later, those who had received exercise only showed less relapse. Researchers suggest that exercise helps patients develop a sense of personal mastery and positive self-regard, which helps patients get over being depressed and decreases the risk of future relapse (Babyak et al., 2000). Other research found that depressed patients who exercised 30 minutes, three to five times a week, reported a 50% reduction in symptoms of depression after 12 weeks (Dunn et al., 2005). Also, researchers found that exercise has an immediate positive effect on mood that lasts for as long as 12 hours (Sibold, 2009). As a treatment for depression, exercise is effective and inexpensive and has no unwanted side effects.

Next, we'll discuss several ways to overcome mild depression.

Photo Credits: top and left, © PhotoLink/PhotoDisc, Inc.

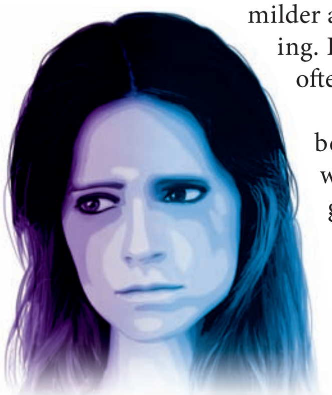
H. Application: Dealing with Mild Depression

Mild Versus Major Depression

How does depression differ?

There is a big difference between mild and major depression. Earlier, we discussed singer Sheryl Crow, who experienced major depressive disorder. Symptoms of major depressive disorder include being in a bad mood for at least two weeks, having no interest in anything, and getting no pleasure from activities. Additionally, to be diagnosed with major depression, a person must have at least two of the following problems: difficulty in sleeping, eating, thinking, and making decisions or having no energy and feeling continually fatigued. Compared with the symptoms of major depressive disorder, the symptoms of mild depression are milder and generally have less impact on a person's functioning. For example, take the case of Janice, who has what is often called the sophomore blues.

"At first I was excited about going off to college and being on my own," explains Janice. "But now I feel worn out from the constant pressure to study, get good grades, and scrape up enough bucks to pay my rent. I've lost interest in classes, I have trouble concentrating, I'm doing poorly on exams, and I'm thinking about changing my major—again. And to make everything even more depressing, my boyfriend just broke up with me. I sit around wondering what went wrong or what I did or why he broke it off. What did I do that was so bad? My friends are tired of my moping around and complaining, and I know they are starting to avoid me. Yeah, everyone says that I should just get over him and get on with my life. But exactly what do I do to get out of my funk?"



There is a big difference between the symptoms of major and mild depression.

Continuum. Some researchers have argued that the kind of depression reported by college students is related to general distress and does not represent any of the particular symptoms and feelings found in major depression (J. C. Coyne, 1994). However, other researchers find that depression is best thought of as a continuum. At one end of the continuum is mild depression, such as that experienced by many college students, which is basically similar in quality but just a milder form of major depression, which is at the other end of the continuum (Flett et al., 1997).

College students. Although many college students experience mild depression, a considerable number also suffer from more severe forms of depression. For instance, a national survey found that 40% of college students have reported feeling "so depressed it's difficult to function," and another 10% reported they had "seriously considered suicide." In fact, more than 5% of students reported they had actually attempted suicide, which is the second leading cause of death among college students, compared to its ranking as the ninth leading cause of death in the general population (ACHA, 2007; NAMH, 2008). These statistics are devastating but perhaps not surprising when you consider that college students are experiencing almost all the major stressors of adulthood, including coping with a new environment, dealing with academic pressures, trying to establish intimate personal relationships, experiencing financial difficulties, and trying to achieve some independence from parents and family (Pennebaker et al., 1990).

Vulnerability. There are three major factors that increase an individual's vulnerability or risk for developing mild depression. The first factor is being a young adult who is facing new, challenging, and threatening situations and feelings. The second factor is having a high number of negative life events. Since college students experience both of these factors, they are at high risk for developing mild depression, which may lead to major depression later in life. The third factor involves an individual's pattern of thinking, which is the basis for Beck's theory of depression.

Beck's Theory of Depression

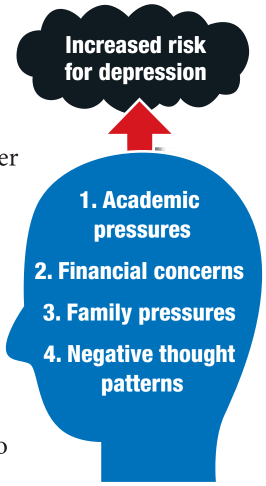
How much do thoughts matter?

Janice thinks that her depression is caused by outside forces, such as academic pressures, financial concerns, personal difficulties, and family pressures. There is no question that stressful events or negative situations can depress Janice's mood. However, another factor that Janice may not be aware of and that may contribute to her depression is a particular pattern of thinking, which is described by Aaron Beck's (1991) cognitive theory of depression.

Beck's cognitive theory of depression says that when we are feeling down, automatic negative thoughts that we rarely notice occur continually throughout the day. These negative thoughts distort how we perceive and interpret the world and thus influence our behaviors and feelings, which in turn contribute to our feeling depressed.

Often these automatic negative thoughts are centered on personal inadequacies, such as thinking one is a failure, is not liked, or never gets anything done. Beck has identified a number of ***specific negative, maladaptive thoughts*** that he believes contribute to developing anxiety and depression. For example, thinking "I'm a failure" after doing poorly on one test is an example of ***overgeneralization***—that is, making a blanket judgment about yourself based on a single incident. Thinking "People always criticize me" is an example of ***selective attention***—that is, focusing on one detail so much that you do not notice other positive events, such as being complimented. Beck believes that maladaptive thought patterns cause a distorted view of oneself and one's world, which in turn may lead to various emotional problems, such as depression. Thus, one of the things that Janice must work on to get out of her depressed state is to identify and change her negative, maladaptive thoughts.

We'll discuss how negative thoughts and two other factors maintain depression, as well as ways to change them.



Overcoming Mild Depression

What can one do?

Once we get "down in the dumps," we are likely to stay there for some time unless we work at changing certain thoughts and behaviors, such as improving social skills, increasing social support, and eliminating negative thoughts. We'll describe several ways to "get out of the dumps" and overcome mild depression.

Improving Social Skills

Problem. In some cases, a person may feel mildly depressed because he or she has poor social skills, which lead to problems in having good social interactions.

Poor social skills can increase chances of feeling depressed.

For example, researchers found that depressed teenagers and college students may be overly dependent, competitive, aggressive, or mistrustful, which in turn caused problems in developing and maintaining close social relationships (M. K. Reed, 1994). If part of being depressed involves poor social skills, a person can learn new ways of interacting with friends.

Program. As with every behavioral change program, the first step is to monitor our social interactions to notice what we are doing wrong, such as complaining too much and irritating our friends. Once we're aware of our bad habits, such as being negative, not asking questions or showing interest, and not being sympathetic, we can begin to take positive steps. That means making a real effort to stop complaining and to show more interest in our friends' activities and to be more sensitive to their feelings. By proceeding in gradual steps, we can learn to improve our social skills and get more rewards from social interactions, which in turn will make us feel better and help us get over our mild depression (Hokanson & Butler, 1992).

Problem. Researchers find that individuals often become and remain mildly depressed because they do not give themselves credit for any success (however small), make every situation (however small) into a bad or unpleasant experience, and constantly blame themselves for every failure, which makes them more depressed and thus elicits more negative reactions from friends (Nurius & Berlin, 1994).

Learning to take credit for our actions can help overcome feelings of mild depression.

Program. The first step in increasing our self-esteem is to become aware of self-blame by monitoring our thoughts and noticing all the times we blame ourselves for things, no matter how small. Once we become aware of self-blame, we can substitute thoughts of our past or recent accomplishments, no matter how small. By substituting thoughts of accomplishment and focusing on recent successes, we will gradually improve our self-esteem. As our self-esteem improves, we will slowly get a more positive attitude, which increases the social support of our friends (Granvold, 1994).

Eliminating Negative Thoughts

Problem. According to Beck's theory of depression, a depressed person thinks negative, maladaptive thoughts, which in turn cause the person to pay attention to, perceive, and remember primarily negative and depressing situations, events, and conversations (A. T. Beck, 1991). Thus, besides improving social skills and increasing social support, depressed individuals also need to stop the automatic negative thought pattern that maintains depression.

Researchers found that depressed individuals have a tendency to select and remember unhappy, critical, or depressing thoughts, events, or remarks, remember fewer good things than bad things, and take a more pessimistic view of life (Corey, 2005). Although discussed later (pp. 574–575), here's a brief description of a program for changing negative thought patterns.

After identifying negative thoughts . . .

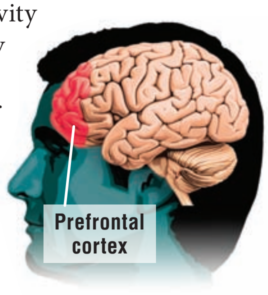
. . . substitute positive thoughts

Program. The first step is to monitor the occurrence of negative, depressive thoughts. The second step is to eliminate depressive thoughts by substituting positive ones. This second step is difficult because it requires considerable effort to stop thinking negative thoughts ("I really am a failure") and substitute positive ones ("I've got a lot going for me"). With practice, we can break the negative thought pattern by stopping negative thoughts and substituting positive ones. These kind of "talk" programs can help a person overcome mild depression and enjoy life more (Freeman et al., 2004). One reason "talk" programs can help as much as antidepressants is that "talk" programs and antidepressants produce strikingly similar changes in the brain.

Power of Positive Thinking

Everyone has heard about the power of positive thinking, and now researchers have found a concrete example. It began with the interesting and reliable finding that psychotherapy ("talk" therapy) can often reduce depressive symptoms as much as antidepressants can (Rupke et al., 2006). Wondering why psychotherapy was as powerful as drugs, researchers took brain scans (pp. 70–71) of patients diagnosed with depression before and after 12 weeks of treatment with either psychotherapy or antidepressants. The result was that both treatments, psychotherapy and antidepressants, decreased depression. But the surprising finding was that both psychotherapy and antidepressants produced similar changes in the brain, one of which was to decrease the abnormally high activity of the prefrontal cortex (right figure) (A. L. Brody et al., 2001).

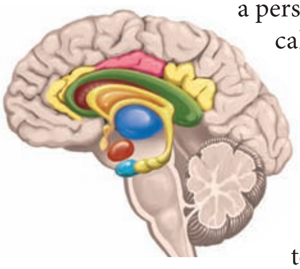
Several studies have now reported similar results: Talk therapy can and does alter brain functioning (Roffman et al., 2005). This means that the next time you are down in the dumps, try the power of positive thinking to change your brain functioning. You may be pleasantly surprised by the happy results.



Summary Test

A. Mood Disorders

1. A disturbed emotional state that affects almost all of a person's thoughts and behaviors is called a ______________ disorder.



2. One mood disorder is marked by being in a daily bad mood, having no interest in anything, getting no pleasure from activities, and having at least four of the following symptoms: problems with weight, appetite, sleep, fatigue, thinking, or making decisions and having suicidal thoughts. This is called (a) ______________ disorder, which is the most common form of mood disorder. Another mood disorder is characterized by being chronically depressed for many but not all days over a long period of time and having two of the following symptoms: problems with appetite and sleep, fatigue, low self-esteem, and feelings of hopelessness. This is called (b) ______________ disorder.

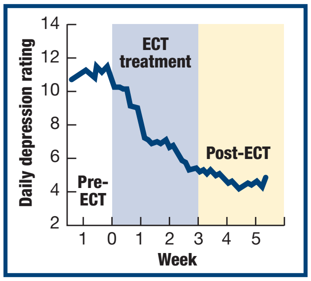
3. A mood episode that is characterized by a distinct period, lasting at least a week, during which a person is unusually euphoric, cheerful, or high and has at least three of the following symptoms—has great self-esteem, needs little sleep, speaks rapidly and frequently, experiences racing thoughts, is easily distracted—is called a (a) ______________ episode. A disorder characterized by periods of fluctuation between episodes of depression and mania is called (b) ______________ disorder.

4. Underlying genetic, neurological, or physiological components may predispose a person to developing a mood disorder. These components are called (a) ______________ factors. Factors such as dealing with stressors and stressful life events are believed to interact with predisposing biological influences and contribute to the development, onset, and maintenance of mood disorders. These are called (b) ______________ factors.

5. Some drugs increase levels of neurotransmitters (serotonin, norepinephrine, dopamine) called (a) ______________. These drugs, which are involved in the regulation of emotions and moods, such as major depression, are called (b) ______________ and may take up to 8 weeks before they begin to work. The newer and more popular antidepressants (Prozac) are called (c) ______________, or SSRIs, and are not more effective but have fewer unwanted (d) ______________ than older antidepressants.

6. A mood stabilizer used to treat bipolar I disorder is called (a) ______________, and it's often combined with antidepressants and antipsychotics. This drug is also used to treat euphoric periods without depression; this disorder is called (b) ______________.

B. Electroconvulsive Therapy



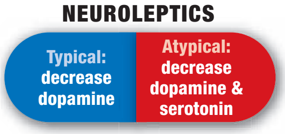
7. If antidepressant drugs fail to treat major depression, the treatment of last resort involves placing electrodes on the skull and administering a mild electric current that passes through the brain and causes a seizure. This treatment is called (a) ______________ therapy. A potentially serious side effect of this treatment is impairment or deficits in (b) ______________, which usually affects events experienced during the weeks of treatment as well as events before and after treatment. However, following ECT treatment, there is a gradual improvement in memory functions.

C. Personality Disorders

8. A disorder that involves inflexible, long-standing, maladaptive traits that cause significantly impaired functioning or great distress in one's personal and social life is called a (a) ______________ disorder. Ten of these disorders are listed in the DSM-IV-TR, including: a pattern of being submissive and clingy because of an excessive need to be taken care of, which is called a (b) ______________ disorder, and a pattern of disregarding or violating the rights of others without feeling guilt or remorse, which is called an (c) ______________ disorder. There is evidence that personality disorders develop from an interaction of (d) ______________ and ______________ factors.

9. Evidence that genetic factors influence personality disorders comes from studies on ______________, which show that genetic factors contribute 30–50% to the development of these personality disorders.

D. Schizophrenia



NEUROLEPTICS
Typical: decrease dopamine
Atypical: decrease dopamine & serotonin

10. Schizophrenia is a serious mental disturbance that lasts for at least six months and includes at least two of the following persistent symptoms: delusions, hallucinations, disorganized speech, grossly disorganized behavior, and decreased emotional expression. These symptoms interfere with personal or social ______________.

11. The DSM-IV-TR lists five subcategories of schizophrenia, which include the following three. A category characterized by bizarre ideas, confused speech, childish behavior, great emotional swings, and often extreme neglect of personal appearance and hygiene is called (a) ______________ schizophrenia. Another

Photo Credit: (#8) © Alan Fredrickson/Reuters/Corbis

form marked by periods of wild excitement or periods of rigid, prolonged immobility is called (b) ________ schizophrenia. A third form characterized by thoughts of being persecuted or thoughts of grandeur is called (c) ________ schizophrenia.

12. Researchers have searched for an identifiable gene or a specific segment of a chromosome that is directly linked to developing schizophrenia. This genetic link is called a ________.

13. Two kinds of neuroleptic drugs are used to treat schizophrenia symptoms by changing levels of neurotransmitters in the brain. Drugs that act primarily to reduce levels of the neurotransmitter dopamine are called (a) ________ neuroleptics. An example is the phenothiazines. Drugs that lower levels of dopamine but, more important, also reduce levels of other neurotransmitters, especially serotonin, are called (b) ________ neuroleptics. These drugs are generally more effective in reducing schizophrenia symptoms and better at preventing (c) ________.

14. One side effect of the continued use of phenothiazines is the appearance of slow, involuntary, and uncontrollable rhythmic movements and rapid twitching of the mouth and lips, as well as unusual movements of the limbs. This side effect is called ________.

15. One theory of schizophrenia says that it develops when the (a) ________ neurotransmitter is overactive. Another related theory says that some people have a genetic predisposition, called a (b) ________, that interacts with life stressors to result in the onset and development of schizophrenia.

E. Dissociative Disorders

16. A dissociative disorder is characterized by a (a) ________ in a person's normally integrated functions of memory, identity, or perception of the environment. The DSM-IV-TR lists five types of dissociative disorder, which include the following three. If a person is unable to recall important personal information or events, usually in connection with a stressful or traumatic event, and the information forgotten is too important or lengthy to be explained by normal forgetfulness, it is called (b) ________. If a person suddenly and unexpectedly travels away from home or place of work and is unable to recall the past and may assume a new identity, it is called (c) ________. If a person experiences the presence of two or more distinct identities or personality states, each with its own pattern of perceiving, thinking about, and relating to the world, it is called (d) ________ disorder.

17. One theory says that dissociative identity disorder (DID) develops as a way to cope with the severe trauma of childhood (a) ________. A second explanation is that DID has become a culturally approved way for people to express their (b) ________ or to control others or gain personal rewards.

F. Cultural Diversity: Interpreting Symptoms

18. Spirit possession is one example of how cultural factors determine whether symptoms are interpreted as (a) ________ or ________. An example of how cultural factors may increase the risk for development of mood disorders can be traced to the differences in assigned (b) ________ roles: Males are expected to be independent and in control, and females are expected to be dependent and not have control.

G. Research Focus: Exercise Versus Drugs

19. After three different treatments, including exercise only, researchers found that at least 60% of patients diagnosed with (a) ________ showed significant improvement. Another finding was that when patients were retested 6 months later, those who had received exercise only showed significantly less (b) ________. Researchers suggest that (c) ________ helps patients develop a sense of personal mastery and positive self-regard, which helps prevent relapse.

H. Application: Dealing with Mild Depression

20. Beck's cognitive theory of depression says that when we are depressed, we have automatically occurring (a) ________, which center around being personally inadequate. In turn, these negative thoughts (b) ________ how we perceive and interpret the world and thus influence our behaviors and feelings. There are effective programs for developing better social skills and eliminating negative thoughts. Psychotherapy and antidepressant drugs both reduced depression and both produced similar changes in how the (c) ________ functions.

Answers: *1. mood; 2. (a) major depressive, (b) dysthymic; 3. (a) manic, (b) bipolar I; 4. (a) biological, (b) psychosocial; 5. (a) monoamines, (b) antidepressants, (c) selective serotonin reuptake inhibitors, (d) side effects; 6. (a) lithium, (b) mania; 7. (a) electroconvulsive, (b) memory; 8. (a) personality, (b) dependent, (c) antisocial, (d) biological, psychological; 9. twins; 10. functioning; 11. (a) disorganized, (b) catatonic, (c) paranoid; 12. genetic marker; 13. (a) typical, (b) atypical, (c) relapse; 14. tardive dyskinesia; 15. (a) dopamine, (b) diathesis; 16. (a) disruption, split, breakdown, (b) dissociative amnesia, (c) dissociative fugue, (d) dissociative identity; 17. (a) physical or sexual abuse, (b) frustrations, fears; 18. (a) normal, abnormal, (b) gender; 19. (a) major depression, (b) relapse, (c) exercise; 20. (a) negative thoughts, (b) bias or distort, (c) brain*

What Is a Psychopath?

Jeffrey Dahmer would pick up young gay men, bring them home, drug them, strangle them, have sex with their corpses, and then, in some cases, eat their flesh.

Dennis Rader would break into people's homes, tie them up, strangle them, and eventually murder them. His murder method earned him the name "BTK killer," which stands for Bind, Torture, and Kill.

Dahmer and Rader share much in common. They are superficially charming, unemotional, impulsive, and self-centered. They are pathological liars who constantly manipulate others. Also, both men completely lack remorse, guilt, and empathy. Finally, they have low self-esteem, a strong desire to be in control, and a lifelong sense of loneliness. Dahmer, for example, felt so lonely that he admitted to killing people for company. Together, the above characteristics define a psychopath.

What may seem surprising is that psychopaths can love their parents, spouses, and children but have great difficulty loving the rest of the world. Rader, for instance, was a loving husband and father. Yet, he seemed completely devoid of humanity as he plainly recounted the details of how he murdered his many victims.

Some of the fascinating characteristics and behaviors of psychopaths may be explained by biological and neurological factors. For example, some psychopaths have abnormalities in their limbic system, which is responsible for motivational behaviors, such as eating and sex, as well as emotional behaviors, such as fear, anger, and aggression. Also, some psychopaths have a disruption in the communication between the hippocampus and the prefrontal cortex, which is believed to contribute to their lack of control, inability to regulate aggression, and insensitivity to cues that predict they will get caught and punished. Interestingly, psychopaths also have lower autonomic arousal and consequently experience less distress when exposed to threats.

The life histories of psychopaths often include a chaotic upbringing, lack of parental attention, parental substance abuse, and child abuse. These life experiences may interact with biological or neurological factors linked to psychopathic behaviors. For instance, children may have genes for psychopathic behaviors that get activated only under stress; if they are raised in a nurturing environment, they may very well develop into well-behaved, moral adults. In other words, at least for some children, the consequences of having a stressful childhood can be deadly. (Adapted from B. Bower, 2006b, 2008e; Crenson, 2005; C. Goldberg, 2003; Hickey, 2006; Larsson et al., 2006; Lilienfeld & Arkowitz, 2007; Martens, 2002; A. Raine et al., 2004; Wilgoren, 2005; Yang et al., 2005b)

QUESTIONS

1 According to the three definitions of abnormal behavior (p. 511), are Dahmer and Rader abnormal?

2 What objective test can be used to best assess for these psychopathic personality traits?

3 Which trait theory can explain how an individual can display such drastically inconsistent behaviors?

4 What part of the limbic system explains how psychopaths can be so cold and fearless?

5 How would a psychopath do on a lie detector test?

6 What is it called when someone has inherited a gene for psychopathic behaviors but develops those behaviors only if he or she has a stressful childhood?

Suggested Answers to Critical Thinking

1. Dahmer and Rader's behaviors are abnormal in terms of statistical frequency, deviation from social norms, and being maladaptive.
2. The Minnesota Multiphasic Personality Inventory-2 (MMPI-2) (p. 474) is an objective personality test that assesses a range of personality traits, including anger, truthfulness, self-esteem, friendliness, and seriously deviant behaviors.
3. The person-situation interaction (p. 464) explains how a person's behavior results from an interaction between his or her traits and the effects of being in a particular situation. It explains how psychopaths, such as Dahmer and Rader, can be loving people with their families but cold-blooded, heartless serial killers in the community.
4. The amygdala (pp. 80, 362) is the structure located in the limbic system that is responsible for evaluating whether stimuli have positive (happy) or negative (fearful, threatening) emotional significance for our survival. Damage to the amygdala explains how psychopaths can completely lack empathy and not learn to fear and avoid dangerous situations, such as cues that predict they will get caught.
5. A lie detector test (pp. 370–371) measures involuntary physiological responses and is based on the theory that a person who lies will feel guilt or fear, which will result in an increase in the galvanic skin response and other physiological responses. Because psychopaths do not feel guilt or fear and do not sweat easily due to lower autonomic arousal, they should pass a lie detector test with flying colors.
6. Having biological or neurological factors for psychopathic behaviors produces a *predisposition* (p. 540) for psychopathic behaviors, which increases the risk or vulnerability of developing such behaviors.

Introduction

Beginning of Psychoanalysis

Why couldn't she drink a glass of water?

It is the late 1800s, and we are listening to a young, intelligent woman named Anna O. She explains that she was perfectly healthy until she was 21 years old, when she began to experience strange physical symptoms. She developed a terrible squint that blurred her vision, a gagging feeling when she tried to drink a glass of water, and a paralysis in her right arm that would spread down her body. These symptoms occurred at about the time her father developed a serious illness and she felt the need to care for him by spending endless hours at his bedside. When her symptoms persisted, she consulted her doctor, Joseph Breuer.

Her right arm became paralyzed with no physical or neurological cause.

Dr. Breuer takes up Anna's story and explains that, during some of her visits, she would sit in a trancelike state and talk uninhibitedly of her past experiences. One time Anna related a childhood incident in which she had watched her governess's dog drink out of a glass. The experience was disgusting to her because she disliked both the governess and the dog. At the time of the incident, Anna had shown no emotional reaction. But as she retold her story, she let out strong emotional reactions that had been locked inside. After releasing these pent-up emotional feelings, she was once again able to drink a glass of water without gagging.

Breuer explains that sometimes hypnosis helped Anna recall painful past experiences. She told of sitting by her father's sickbed, falling asleep, and having a horrifying dream in which a snake attacked him. She could not reach out and stop the snake because her arm had fallen asleep from hanging over the chair. As Anna relived her powerful guilt feelings of not being able to protect her father, the paralysis of her right arm disappeared. Breuer describes how, each time Anna recalled a past traumatic experience, a physical symptom associated with that trauma would vanish. Breuer would often discuss Anna's case with his friend and colleague, Sigmund Freud.

Dr. Freud interpreted Anna's symptoms as being caused by strong, primitive forces, probably related to unconscious sexual desires (Breuer & Freud, 1895/1955). The case of Anna O. is important because it played a role in the development of Freud's system of psychoanalysis, which was the start of what we currently call psychotherapy.

Just as psychoanalysis had its beginning with Anna O., another very different kind of therapy had its beginning with Little Albert.

Beginning of Behavior Therapy

Why was Albert afraid of a white rat?

It was the early 1900s when John Watson, an up-and-coming behaviorist, showed 9-month-old Albert a number of objects to see if any caused fear. Little Albert looked at a white rat, rabbit, dog, monkey, several masks, pieces of wool, and burning newspapers without showing the slightest sign of fear.

Later, when Albert was about 11 months old, Watson retested Albert. This time, as Albert sat on a mattress, Watson suddenly took a white rat out of a basket and showed it to Albert. At the very moment Albert touched the animal, another experimenter standing behind Albert struck a steel bar with a hammer. The sudden loud noise made Albert jump violently and fall forward into the mattress. Five more times Watson showed Albert the white rat and each time a loud sound rang out from behind. Finally, Watson showed Albert the rat but there was no loud sound. The instant the rat appeared, Albert began to cry and turn away from the rat. From this demonstration, Watson concluded that he had shown, for the first time, that an emotional reaction—in this case, fear—could be conditioned to any stimulus (Watson & Rayner, 1920).

This white rat caused no fear until . . .

. . . Little Albert was classically conditioned.

The case of Little Albert could be considered the starting point for a very different kind of psychotherapy, known as behavior therapy. Behavior therapists believe that emotional problems may arise through conditioning and thus may be treated—or unconditioned—by using other principles of learning.

The cases of Little Albert and Anna O. illustrate two very different assumptions about how psychotherapy works. According to behavior therapy, emotional problems are learned and thus can be unlearned through conditioning techniques. According to psychoanalysis, emotional problems arise from unconscious fears, which can be uncovered and revealed only with special techniques. We'll discuss these two assumptions along with those of several other therapies as well as whether different therapies produce different results.

What's Coming

In this module we'll discuss the history of psychotherapy and how current therapists are trained. We'll explain Freud's psychoanalysis and how those who disagreed with Freud developed their own kinds of therapies. We'll discuss three of the more popular forms of psychotherapy: behavior therapy, cognitive therapy, and humanistic therapy. Finally, we'll answer one of the most interesting questions: Do therapies differ in their effectiveness?

Let's begin with how psychotherapy came about and how it has developed into a multibillion-dollar business.

A. Historical Background

Definition

Today, there are over 400 different forms of psychotherapy, some of them tested and some based purely on personal beliefs. For example, some states do not require the licensing of therapists; almost anyone can hang out a sign and go into practice (M. T. Singer & Lalich, 1997). The remaining states require licensing and training of therapists. There are about a dozen tested psychotherapies that may differ in assumptions and methods but generally share the following three characteristics.

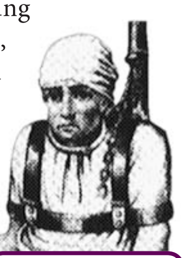
Psychotherapy **has three basic characteristics: verbal interaction between therapist and client(s); the development of a supportive relationship in which a client can bring up and discuss traumatic or bothersome experiences that may have led to current problems; and analysis of the client's experiences and/or suggested ways for the client to deal with or overcome his or her problems.**

We'll discuss the major changes in treating mental disorders, including early inhumane treatments, the breakthrough in the use of drugs, and community mental health centers.

Early Treatments

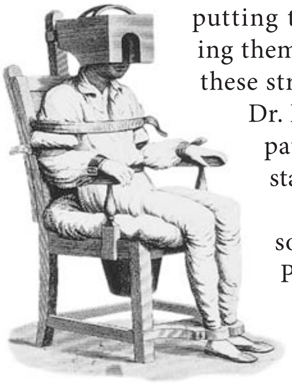
Why did hospitals sell tickets?

From 1400 to 1700, people who today would be diagnosed as schizophrenics were considered insane and called lunatics. They were primarily confined to asylums or hospitals for the mentally ill, where the treatment was often inhumane and cruel. For example, patients were treated by being placed in a hood and straitjacket, chained to a cell wall, swung back and forth until they were quieted, strapped into a chair (right drawing), locked in handcuffs, hosed down with water until they were exhausted, or twirled until they passed out.



Early treatment was to be strapped to a chair.

In the late 1700s, Dr. Benjamin Rush, who is considered the father of American psychiatry, developed the "tranquilizing chair" (bottom drawing). A patient was strapped into this chair and remained until he or she seemed calmed down. Dr. Rush believed that mental disorders were caused by too much blood in the brain. To cure this problem, he attempted to treat patients by withdrawing huge amounts of blood, as much as six quarts over a period of months. Dr. Rush also tried to cure patients with fright, such as putting them into coffins and convincing them they were about to die. Despite these strange and inhumane treatments, Dr. Rush encouraged his staff to treat patients with kindness and understanding (Davison & Neale, 1994).



Early treatment was to sit in a "tranquilizing chair."

In the 1700s, some hospitals even sold tickets to the general public. People came to see the locked-up "wild beasts" and to laugh at the tragic and pathetic behaviors of individuals with severe mental disorders. However, in the late 1700s and early 1800s, a few doctors began to make reforms by removing the patients' chains, forbidding physical punishment, and using a more psychological approach to treat mental disorders (J.C. Harris, 2003).

Reform Movement

What did she change?

In the 1800s, a Boston schoolteacher named Dorothea Dix (right photo below) began to visit the jails and poorhouses where most of the mental patients in the United States were kept. Dix publicized the terrible living conditions and the lack of reasonable treatment of mental patients. Her work was part of the reform movement that emphasized moral therapy.

Dorothea Dix began the humane treatment of the mentally ill.

Moral therapy, **which was popular in the early 1800s, was the belief that mental patients could be helped to function better by providing humane treatment in a relaxed and decent environment.**

During the reform movement, pleasant mental hospitals were built in rural settings so that moral therapy could be used to treat patients. However, these mental hospitals soon became overcrowded, the public lost interest, funds became tight, and treatment became scarce.

By the late 1800s, the belief that moral therapy would cure mental disorders was abandoned. Mental hospitals began to resemble human snake pits, in which hundreds of mental patients, in various states of dress or undress, milled about in a large room while acting out their symptoms with little or no supervision. Treatment went backward, and once again patients were put into straitjackets, handcuffs, and various restraining devices (Routh, 1994).

Psychoanalysis

Freud developed first psychotherapy.

By the early 1900s, Sigmund Freud had developed psychoanalysis, the first psychotherapy. Psychoanalysis eventually spread from Europe to the United States and reached its peak of popularity in the 1950s. However, psychoanalysis was more effective in treating less serious mental disorders (neuroses) than in treating the serious mental disorders (psychoses) that kept people in mental hospitals.

Thus, the wretched conditions and inhumane treatment of patients with serious mental disorders persisted until the early 1950s. By then, more than half a million patients were locked away. But in the mid-1950s, two events dramatically changed the treatment of mental patients: one was the discovery of antipsychotic drugs, and the other was the development of community mental health centers.

Phenothiazines and Deinstitutionalization

What was the first breakthrough?

The discovery of drugs for treating mental disorders often occurs by chance. Such was the case in the 1950s as a French surgeon, Henri Laborit, searched for a drug that would calm down patients before surgery without causing unconsciousness. He happened to try a new drug on a woman about to have surgery and who was also schizophrenic. To the doctor's great surprise, the drug not only calmed the woman down but also decreased her schizophrenic symptoms. This is how the drug, chlorpromazine, was discovered to be a treatment for schizophrenia. Chlorpromazine *(klor-PRO-ma-zeen)* belongs to a group of drugs called phenothiazines.

Phenothiazines *(fee-no-THIGH-ah-zeens),* which were discovered in the early 1950s, block or reduce the effects of the neurotransmitter dopamine and reduce schizophrenic symptoms, such as delusions and hallucinations.

After 200 years of often cruel and inhumane treatments for mental disorders, chlorpromazine was the first drug shown to be effective in reducing severe mental symptoms, such as delusions and hallucinations. For this reason, the discovery of chlorpromazine is considered the first revolution in the drug treatment of mental disorders. Earlier we discussed the phenothiazines, now called typical neuroleptics, as well as the newer discovery of atypical neuroleptics (p. 541), which are used in the treatment of schizophrenia.

In 1954, one of the phenothiazines, chlorpromazine (trade name: Thorazine), reached the United States and had two huge effects. First, it stimulated research on neurotransmitters and on the development of new drugs to treat mental disorders. Second, chlorpromazine reduced severe mental symptoms such as delusions and hallucinations to the point that patients could function well enough to be released from mental hospitals, a policy called deinstitutionalization.

Deinstitutionalization refers to the release of mental patients from mental hospitals and their return to the community to develop more independent and fulfilling lives.

In 1950, before the discovery of phenothiazines, there were 550,000 patients in mental hospitals in the United States. After the use of phenothiazines and deinstitutionalization, the number of patients in mental hospitals had dropped to about 150,000 in 1970 and to about 80,000 in 2000 (Manderscheid & Sonnenschein, 1992). However, deinstitutionalization has created a related problem.

Homeless. The goal of deinstitutionalization, which is to get patients back into the community, has been only partly realized. Some former mental patients do live in well-run halfway houses (F. R. Lipton et al., 2000). However, recent investigations have found that some halfway houses are poorly maintained, use untrained staff, and provide little or no treatment for the residents. The major problems are lack of funding and poor supervision of halfway houses.

About 25–80% of the homeless have some degree of mental problems.

Because there are not enough good halfway houses, many deinstitutionalized patients end up on the streets and homeless. The result is that about 25–80% of today's homeless individuals have serious mental disorders and receive little or no treatment (Hartwell, 2003; USCM, 2007). To provide mental health treatment for the homeless as well as those released from hospitals or too poor to pay for services, there is another place to receive help—community mental health centers.

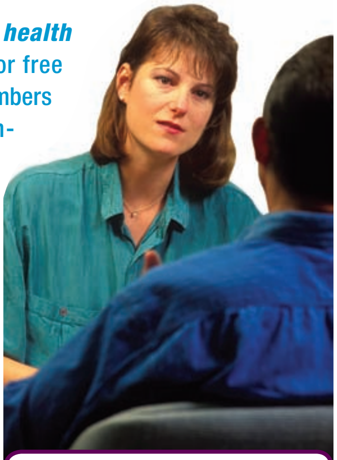
Photo Credits: left, © AP Images/Rusty Kennedy; right, © Mira/Alamy

Community Mental Health Centers

Where can they go for treatment?

There is a need for treatment of mental disorders in the homeless, county prisoners, those released from mental hospitals, as well as about 26% of Americans who experience a mental disorder in the course of a year (NIMH, 2008b). Some of these individuals may have less serious mental disorders that require professional help but not hospitalization. One way to provide professional help to individuals with less serious mental disorders is through community mental health centers.

Community mental health centers offer low-cost or free mental health care to members of the surrounding community, especially the underprivileged. The services may include psychotherapy, support groups, and telephone crisis counseling.



Therapist is treating a client in a community mental health center, which helps those who need care but can't afford it.

Just as the 1950s saw the introduction of a new drug treatment for mental disorders (phenothiazines), the 1960s saw the growing availability of new treatment facilities, community mental health centers. The goal of these centers as well as other outpatient centers is to provide treatment for the poor and those who have no other forms of treatment for their mental health problems. These kinds of mental health centers provide briefer forms of therapy that are needed in emergencies and focus on the early detection and prevention of psychological problems. To meet these ambitious goals required an enormous increase in the number of mental health personnel (Burns, 2004; J. Rosenberg, 2006).

In the 1960s, ***psychiatrists*** provided the majority of psychological services, which consisted of mainly psychoanalysis and served individuals in the middle and upper social classes who were not very seriously disturbed. Because of the limited number of psychiatrists, community mental health centers turned to ***clinical psychologists*** and ***social workers*** to provide the new mental health services. This demand increased the number of clinical and counseling psychologists and social workers and stimulated the development of new therapy approaches (Garfield & Bergin, 1994).

Before discussing specific psychotherapies, we'll answer four general questions about psychotherapy.

B. Questions about Psychotherapy

What do I need to know?

If you or a family member, friend, relative, or acquaintance has a mental health problem, there are at least four questions that you might ask about seeking professional help or psychotherapy: Do I need professional help? Are there different kinds of therapists? What are the different approaches? How effective is psychotherapy? We'll answer each question in turn.

Do I Need Professional Help?

Each year, more than 30 million Americans need help in dealing with a variety of mental disorders (NIMH, 2009a). For example, a person may feel overwhelmed by a sense of sadness, depression, or helplessness so that he or she cannot form a meaningful relationship. A person may worry or expect such terrible things to happen that he or she cannot concentrate or carry out everyday activities. A person may become so dependent on drugs that he or she has difficulty functioning in personal, social, or professional situations. If these problems begin to interfere with daily functioning in social, personal, business, academic, or professional interactions and activities, then a person may need help from a mental health professional (APA, 2009a).

Each year, about 30 million Americans need help in dealing with mental disorders.

One reason individuals do not seek professional help involves the social stigma attached to having a mental disorder. For example, in an earlier module, we discussed how well-known singer-songwriter Sheryl Crow suffered from major depression for several years before being persuaded by her mother to seek professional help (p. 532). Although still present, the stigma of having a mental disorder is decreasing as people recognize the need for professional treatment (Alonso et al., 2009; Golberstein et al., 2008).

Another reason individuals do not seek professional help is that they don't realize they need it. In an earlier module, we discussed the case of Michael McCabe, who heard voices and believed people were going to steal things from him (schizophrenia); and in another case, Chuck Elliot went sleepless for four nights and had trouble controlling his behavior (bipolar I disorder) (p. 531). Although both of these individuals needed professional treatment, neither wanted or asked for it. Thus, in some cases, individuals with serious mental disorders may not be able to decide what is best, and their friends or family may need to help them get professional help.

Currently, there are a number of different kinds of mental health professionals who may provide a drug or nondrug treatment program or some combination.

Are There Different Kinds of Therapists?

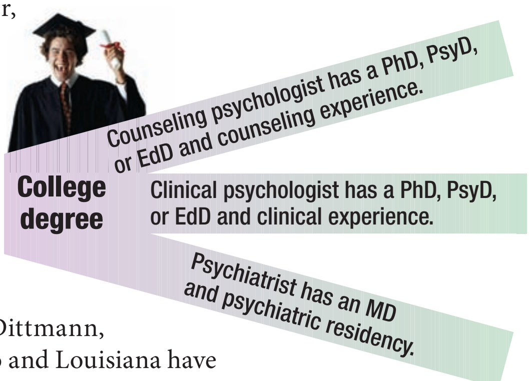
We'll discuss three of the more common kinds of therapists: psychiatrists, clinical psychologists, and counseling psychologists, each of whom receives a different kind of training in psychotherapy techniques. Together, they provide psychotherapy to 3% of the U.S. population each year (Weissman et al., 2006).

Psychiatrists go to medical school, receive an MD degree, and then take a psychiatric residency, which involves additional training in pharmacology, neurology, psychopathology, and psychotherapeutic techniques.

Psychiatrists usually prescribe drugs to treat mental health disorders. Since the 1990s, psychiatrists have been providing less psychotherapy and instead focusing primarily on biological factors. Currently, less than 30% of psychiatrist office visits involve psychotherapy (Westly, 2008).

Clinical psychologists go to graduate school in clinical psychology and earn a doctorate degree (PhD, Psy, or EdD). This training, which includes one year of work in an applied clinical setting, usually requires five to six years of work after obtaining a college degree.

Clinical psychologists focus on psychosocial and environmental factors and use psychotherapy to treat mental health disorders. They generally cannot prescribe drugs. However, in a trial program, clinical psychologists were trained in prescribing drugs for a variety of mental disorders. Evaluators of this program concluded that, with proper training, clinical psychologists can provide high-quality drug treatment for their patients (Dittmann, 2003). Since then, New Mexico and Louisiana have passed laws that allow psychologists with advanced medical training to prescribe medications for patients with mental disorders. Several other states may soon pass similar legislation giving psychologists the right to prescribe medication (Munsey, 2008a, 2008b). For political and financial reasons, psychiatrists oppose laws that allow specially trained psychologists to prescribe drugs (Munsey, 2006; R. J. Sternberg, 2003c).



College degree
Counseling psychologist has a PhD, PsyD, or EdD and counseling experience.
Clinical psychologist has a PhD, PsyD, or EdD and clinical experience.
Psychiatrist has an MD and psychiatric residency.

Counseling psychologists go to graduate school in psychology or education and earn a doctorate degree (PhD, PsyD, or EdD). This training, which includes work in a counseling setting, usually requires about four to six years after obtaining a bachelor's degree.

Counseling psychologists receive training similar to that of clinical psychologists but with less emphasis on research and more emphasis on counseling in real-world settings. Counseling psychologists, who function in settings such as schools, industry, and private practice, generally deal more with problems of living than with the mental disorders that are treated by clinical psychologists.

In addition, other mental health professionals, such as ***clinical social workers*** and ***psychiatric nurses,*** provide mental health services.

Just as there are different kinds of therapists, there are also different kinds of therapeutic approaches from which to choose.

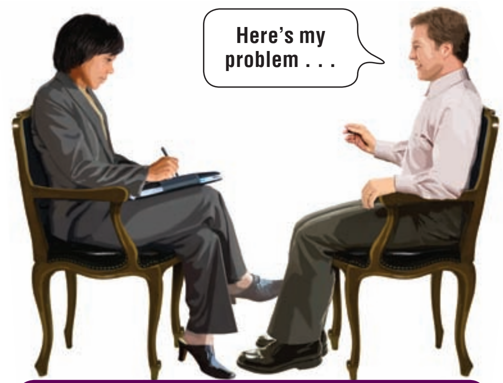
Photo Credit: right, © PhotoDisc, Inc.

What Are the Different Approaches?

If you were to seek professional help for a mental problem, you could choose from a number of different therapeutic approaches: Some use primarily psychotherapy, some use primarily drugs, and others use a combination of psychotherapy and drugs. These different therapies can be divided into three groups: insight therapy, cognitive-behavioral therapy, and medical therapy.

With ***insight therapy,*** the therapist and client talk about the client's symptoms and problems with the goal of reaching or identifying the cause of the problem. Once the client has an insight into the cause of the problem, possible solutions can be discussed with the therapist.

The classic example of insight therapy is psychoanalysis, whose goal is to help clients get insights into their problems. But because psychoanalysis requires hundreds of sessions, it is very costly; and because it is no more effective than other, briefer therapies, its popularity has significantly decreased since the 1950s. The next kind of therapy, called cognitive-behavioral therapy, combines some features of insight therapy with a much more directive approach.



There are several kinds of drug and nondrug therapies for mental disorders.

Cognitive-behavioral therapy involves the application of principles of learning that were discussed in Modules 9 and 10. The therapist focuses on the client's problem, identifies specific thoughts and behaviors that need to be changed, and provides techniques based on learning principles to make desired changes.

Unlike psychoanalysis, which focuses on insight and gives little direction for change, cognitive-behavioral therapy focuses on changing specific undesirable or problematic thoughts and behaviors. This approach combines techniques and ideas from cognitive therapy (p. 565) and behavior therapy (p. 566). Cognitive-behavioral therapy is an example of the most popular approach, which is used by 25–33% of therapists and is called the eclectic approach (Norcross, 2005).

The ***eclectic*** *(e-KLEK-tik)* ***approach*** involves combining and using techniques and ideas from many different therapeutic approaches.

For example, a therapist using an eclectic approach might combine some of the nondirective techniques from psychoanalysis with more directive techniques from cognitive-behavioral therapy. Unlike insight and cognitive-behavioral approaches, which focus on psychosocial factors, the next kind of therapy focuses on changing biological factors.

Medical therapy involves the use of various psychoactive drugs to treat mental disorders by changing biological factors, such as the levels of neurotransmitters in the brain.

In Modules 22 and 23, we discussed medical therapies and how various psychoactive drugs are used to treat a wide variety of mental disorders, including anxiety, mood disorders, and schizophrenia. Unlike medical therapies, in which drugs may have undesirable physical side effects, no undesirable side effects are associated with psychotherapy. In this module, we'll focus on several psychotherapies, specifically insight and cognitive-behavioral approaches.

A number of different drugs (neuroleptics, antidepressants) may be used to treat more serious mental disorders.

With so many different therapeutic approaches, is one kind of psychotherapy more effective than another?

Photo Credit: bottom, © S. Wanke/PhotoDisc, Inc.

How Effective Is Psychotherapy?

Sometimes when we have a problem, we might say, "I'll just wait, and maybe the problem will go away by itself." This kind of remark raises a major question: Is psychotherapy more effective than just waiting for problems to go away? To answer this question and determine the effectiveness of psychotherapy, researchers have used a complex statistical procedure called meta-analysis.

Meta-analysis is a powerful statistical procedure that compares the results of dozens or hundreds of studies to determine the effectiveness of some variable or treatment examined in these studies.

Researchers have done meta-analysis on more than 1,500 studies that examined the effects of psychotherapy on a variety of problems, such as depression, anxiety disorders, family problems, eating disorders, and headaches (Butler et al., 2006; L. Luborsky et al., 2002; P. E. Nathan et al., 2000). We'll discuss three of the major findings:

- Psychotherapy was effective in relieving a wide variety of psychological and behavioral symptoms in comparison with control groups who were on a waiting list to receive therapy or who received no systematic treatment.
- There was little or no significant difference in effectiveness among the approaches used by different therapies. In other words, the same psychological or behavioral symptoms were, in most cases, treated effectively with different approaches.
- The vast majority of patients (75%) showed measurable improvement by the end of six months of once-a-week psychotherapy sessions (24 sessions).

✓ Mood Disorder
✓ Anxiety Disorder
✓ Relationship Problem
✓ Eating Disorder
✓ Substance Use Disorder

Psychotherapy has proved effective for a wide variety of mental disorders.

Thus, based on data from thousands of patients, psychotherapy has proved effective in treating many mental and behavioral problems, and the greatest improvement occurs in a relatively brief time (13 to 18 sessions) (M. J. Lambert et al., 2004). However, the amount of improvement varies across patients (G. S. Brown et al., 2005; Sotsky et al., 2006).

Although many different therapies have been shown to be about equally effective, we'll discuss why some therapeutic approaches are preferred for certain problems and why some clients may prefer one approach over another (Chambless & Ollendick, 2001; O'Donahue & Fisher, 2009).

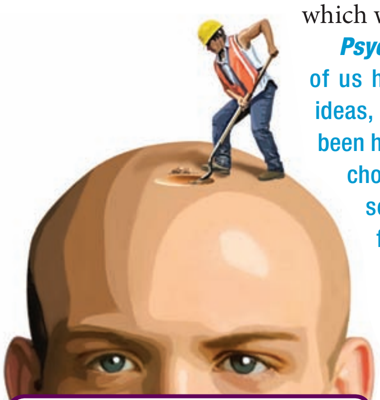
We'll begin with one of the oldest and best-known therapy approaches—Freud's system of psychoanalysis.

C. Insight Therapies

Psychoanalysis

What happens in psychoanalysis?

One reason almost everyone knows the name Freud is that he constructed one of the first amazingly complete and interesting descriptions of personality development, mental disorder, and treatment, which was a monumental and revolutionary accomplishment at the time. In fact, Sigmund Freud's theory of psychoanalysis includes two related theories. The first is his comprehensive theory of personality development (id, ego, superego, and psychosexual stages), which we discussed in Module 19. His second theory involves the development and treatment of various mental disorders, which we'll examine here.



Freud's psychoanalysis searches for unconscious conflicts that result in psychological problems.

Psychoanalysis focuses on the idea that each of us has an unconscious part that contains ideas, memories, desires, or thoughts that have been hidden or repressed because they are psychologically dangerous or threatening to our self-concept. To protect our self-concept from these threatening thoughts and desires, we automatically build a mental barrier that we cannot voluntarily remove. However, the presence of these threatening thoughts and desires gives rise to unconscious conflicts, which, in turn, can result in psychological and physical symptoms and mental disorders.

Freud began developing the theory of psychoanalysis in the late 1800s. From 1902 onward, a number of young doctors and interested laypersons gathered around Freud to learn the principles and practice of psychoanalysis. In 1908, Freud was invited to America to discuss his approach. Psychoanalysis makes three major assumptions (Corey, 2009; E. B. Luborsky et al., 2008).

1 Freud believed that ***unconscious conflicts*** were the chief reason for the development of psychological problems (such as paranoia) and physical symptoms (such as loss of feeling in a hand). To overcome psychological and physical problems, patients needed to become aware of, and gain insight into, their unconscious conflicts and repressed thoughts.

2 Freud developed ***three techniques***—free association, dream interpretation, and analysis of slips of the tongue—that he believed provide clues to unconscious conflicts and repressed thoughts.

3 Freud found that at some point during therapy the patient would react to the therapist as a substitute parent, lover, sibling, or friend and, in the process, project or ***transfer*** strong emotions onto the therapist.

Freud developed these three assumptions gradually, over a period of about ten years, when he was treating patients for a variety of psychological problems and physical symptoms.

We'll explain how Freud used these three assumptions to develop the therapy he called psychoanalysis.

Therapy session. To give you an appreciation of what happens during psychoanalysis, we'll begin with an excerpt from a therapy session and then explain what goes on between client and psychoanalyst.

Henry is in his mid-forties and is well advanced in treatment. As he arrives, he casually mentions his somewhat late arrival at the analyst's office, which might otherwise have gone unnoticed.

"You will think it is a resistance," Henry remarked sarcastically, "but it was nothing of the kind. I had hailed a taxi that would have gotten me to the office on time. However, the traffic light changed just before the cab reached me, and someone else got in instead. I was so annoyed that I yelled 'F___ you!' after the cab driver."

A brief pause ensued, followed by laughter as Henry repeated "F___ you!"—this time clearly directed to the analyst.

The analyst interpreted this interaction to mean that the cabbie had represented the analyst in the first place. Henry's anger at the analyst was relieved by the opportunity to curse out the analyst (cabbie).

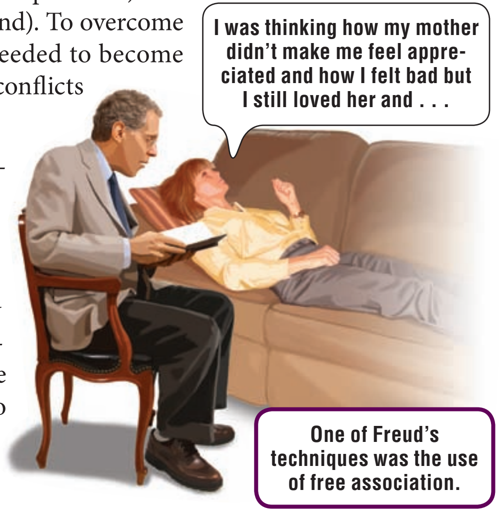
After another brief pause, it was the analyst who broke the silence and injected his first and only interpretation of the 50-minute session. He asserted that Henry seemed to be angry about a previously canceled therapy session.

Henry was furious over the interpretation. "Who are you that I should care about missing that session?" he stormed.

Henry paused again, and then reflected more tranquilly, "My father, I suppose."

This time it was the word *father* that served as the switch word to a new line of thought.

"My father was distant, like you," he began. "We never really had a conversation" (adapted from S. D. Lipton, 1983).



I was thinking how my mother didn't make me feel appreciated and how I felt bad but I still loved her and . . .

One of Freud's techniques was the use of free association.

Role of the Analyst

This brief excerpt from a psychoanalytic session illustrates the basic assumptions of psychoanalysis.

- **Free association.** Notice that the patient is encouraged to free-associate or say anything that comes into his mind, while the analyst makes few comments.
- **Interpretation.** When the analyst does comment, he or she interprets or analyzes something the patient says, such as the meaning of the anger at the cab driver.
- **Unconscious conflicts.** By analyzing the client's free associations, the analyst hopes to reveal the client's unconscious and threatening desires, which are causing unconscious conflicts that, in turn, cause psychological problems.

We'll examine two of Freud's therapy techniques in more detail.

Figure/Text Credit: Therapy session adapted from "A Critique of So-Called Standard Psychoanalytic Technique," by S. D. Lipton, 1983, *Contemporary Psychoanalysis, 19,* 35–52.

Techniques to Reveal the Unconscious

One of Freud's major challenges was to find ways to uncover unconscious conflicts, which, he believed, led to psychological problems that he labeled neuroses.

Neuroses, **according to Freud, are maladaptive thoughts and actions that arise from some unconscious thought or conflict and indicate feelings of anxiety.**

In order to treat neuroses or neurotic symptoms, such as phobias, anxieties, and obsessions, Freud wanted to discover what was in the patient's unconscious. To do this, he developed two major techniques: free association and dream interpretation. To show how these techniques work, we'll describe two of Freud's most famous cases, Rat Man and Wolf-Man.

Rat Man: Free Association

Freud encouraged patients to relax, sit back, or lie down on his now-famous couch and engage in something called free association.

Free association **is a technique that encourages clients to talk about any thoughts or images that enter their heads; the assumption is that this kind of free-flowing, uncensored talking will provide clues to unconscious material.**

For example, here is how Freud described a session with one of his most famous patients, a 29-year-old lawyer later named the Rat Man because of his obsession that rats would destroy his father and lover.

Rat Man believed that rats would destroy his father and lover.

Freud writes, "The next day I made him [Rat Man] pledge himself to submit to the one and only condition of the treatment—namely, to say everything that came into his head even if it was *unpleasant* to him, or seemed *unimportant* or *irrelevant* or *senseless.* I then gave him leave to start his communications with any subject he pleased" (Freud, 1909/1949, p. 297; italics in the original).

Freud is actually telling Rat Man to free-associate. By this means, Freud uncovered a number of Rat Man's repressed memories, such as how Rat Man, as a child, would get into rages and bite people, just like a rat.

Free association was one of Freud's important methodological discoveries. Psychoanalysts still use this technique today to probe a client's unconscious thoughts, desires, and conflicts (Corey, 2009).

Wolf-Man: Dream Interpretation

Freud listened to and interpreted his patients' dreams because he believed that dreams represent the purest form of free association.

Dream interpretation **is a psychoanalytic technique based on the assumption that dreams contain underlying, hidden meanings and symbols that provide clues to unconscious thoughts and desires.**

For example, here is one of the best-known dreams in psychoanalytic literature. This dream was told to Freud by a 23-year-old patient who was later named Wolf-Man because he had a phobia of wolves and other animals (P. Buckley, 1989).

Wolf-Man dreamed wolves were sitting in the tree outside his room.

"I dreamt that it was night and that I was lying in my bed. Suddenly the window opened of its own accord, and I was terrified to see that some white wolves were sitting on the big walnut tree in front of the window. There were six or seven of them. The wolves were quite white, and looked more like foxes or sheep-dogs, for they had big tails like foxes and they had their ears pricked like dogs when they are attending to something. In great terror, evidently of being eaten up by the wolves, I screamed and woke up. . . . I was 3, 4, or at most 5 years old at the time. From then until my 11th or 12th year I was always afraid of seeing something terrible in my dreams" (Freud, 1909/1949, p. 498).

Freud's interpretation of this dream was that, as a young boy, Wolf-Man was "transformed" into a wolf and had witnessed his parents' sexual intercourse (looking through the bedroom window). Later, sexual fears created unconscious conflicts and resulted in a phobia of wolves and other animals.

As Freud demonstrates, the psychoanalyst's task is to look behind the dream's often bizarre disguises and symbols and decipher clues to unconscious, repressed memories, thoughts, feelings, and conflicts (R. Greenberg & Perlman, 1999).

Case Studies: Anna O., Rat Man, and Wolf-Man

Case studies, such as those of Rat Man, Wolf-Man, and Anna O., whom we discussed at the beginning of the module, were very important because from these Freud developed the major concepts of psychoanalysis. For example, from cases like that of Anna O., who had physical symptoms (paralyzed arm, blurred vision) but no apparent physical causes, Freud developed the idea that repressed feelings and unconscious conflicts could affect behavior but that the person would have no awareness of this happening. In support of Freud's belief that unconscious forces were causing Anna O.'s physical problems, each time she let out some apparently repressed emotional experience, one of her physical symptoms disappeared.

Were Anna O.'s physical symptoms caused by unconscious forces?

Freud's case studies read like mystery stories with Freud being the master detective who searches for psychological clues that will reveal the person's repressed feelings and unconscious conflicts. At the time, Freud's assumptions and theories, such as repressed feelings and unconscious motivation, were revolutionary. However, as we'll discuss later, Freud's theories and assumptions have been very difficult to verify or prove with experimental methods.

Besides developing methods to reveal unconscious thoughts and conflicts, Freud discovered two other concepts that are central to psychoanalysis.

C. Insight Therapies

Problems during Therapy

Why did clients get angry?

Freud was the first to notice that, during therapy, his clients became somewhat hostile toward him, a problem he called transference. He also found that patients became very resistant about dealing with their feelings. Freud believed that how these two problems, called transference and resistance, were handled determined how successful therapy would be. We'll explain these two concepts by using the cases of Rat Man and Wolf-Man.

Rat Man: Transference

Freud describes a patient, later labeled Rat Man, as expressing powerful, aggressive feelings toward him. For example, Rat Man refused to shake hands with Freud, accused Freud of picking his nose, called Freud a "filthy swine," and said that Freud needed to be taught some manners (Freud, 1909/1949).

During therapy, Rat Man called Freud a "filthy swine," which Freud believed resulted from transference.

According to Freud, Rat Man was projecting negative traits of his own very controlling mother onto Freud, who became a "substitute mother." This process of transferring feelings to the therapist is called transference.

Transference **is the process by which a client expresses strong emotions toward the therapist because the therapist substitutes for someone important in the client's life, such as the client's mother or father.**

Freud believed that the main part of therapy involved working through the transference—that is, resolving the emotional feelings that the client has transferred to the therapist. Freud said that if the feelings involved in transference were not worked out, therapy would stall and treatment would not occur. For this reason, Freud believed that one of the major roles of the analyst was to help the client deal with, work through, and resolve the transferred feelings. Identifying the process of transference, which occurs in many therapeutic relationships, is considered one of Freud's greatest insights (Eagle, 2000).

Wolf-Man: Resistance

For most patients, working out transference and achieving insight into their problems are long and difficult processes. One reason for the difficulty is that the client has so many defenses against admitting repressed thoughts and feelings into consciousness. These defenses lead to resistance.

Resistance **is characterized by the client's reluctance to work through or deal with feelings or to recognize unconscious conflicts and repressed thoughts.**

Resistance may show up in many ways: Clients may cancel sessions or come late, argue continually, criticize the analyst, or develop physical problems. For example, the patient named Wolf-Man constantly complained of severe constipation. Freud said that Wolf-Man used constipation as an obvious sign that he was resisting having to deal with his feelings (Freud, 1909/1949).

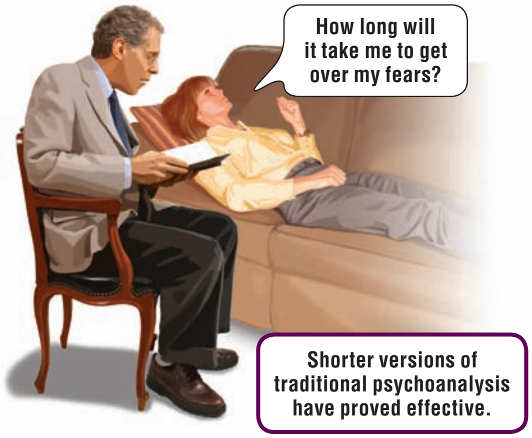
Freud overcame Wolf-Man's resistance by promising that his constipation would disappear with continued therapy, and it did (P. Buckley, 1989). Freud cautioned that the analyst must use tact and patience to break down the client's resistance so that the client faces his feelings.

During therapy, Wolf-Man complained of constipation, which Freud believed indicated resistance.

A necessary role of the analyst is to overcome the client's resistance so the therapy can proceed and stay on course (E. B. Luborsky et al., 2008).

Short-Term Dynamic Psychotherapy

The cases of Rat Man and Wolf-Man illustrate two problems that psychoanalysts must solve before their clients can get better. One problem involves the strong emotional feelings that occur with transference, which must be resolved before therapy can succeed. The second problem is helping clients overcome their resistance so they can begin to deal with threatening or undesirable feelings. Resolving the problems of transference and resistance may take 200 to 600 sessions across several years of traditional psychoanalysis. However, there is currently a strong push toward shorter versions of psychotherapy, in large part because current health insurance coverage typically pays for only 20 to 30 sessions. As a result, therapists have developed a briefer version of psychoanalysis, which is called short-term dynamic psychotherapy (Prochaska & Norcross, 2010).



How long will it take me to get over my fears?

Shorter versions of traditional psychoanalysis have proved effective.

Short-term dynamic psychotherapy **emphasizes a limited time for treatment (20 to 30 sessions) and focuses on limited goals, such as solving a relatively well-defined problem. Therapists take a more active and directive role by identifying and discussing the client's problems, resolving issues of transference, interpreting the patient's behaviors, and offering an opportunity for the patient to foster changes in behavior and thinking that will result in more active coping and an improved image of oneself.**

Several forms of short-term dynamic psychotherapy have recently become more popular than long-term traditional psychoanalysis. Short-term dynamic psychotherapy, which incorporates techniques of traditional psychoanalysis, has proven effective for treating a number of problems, including generalized anxiety, panic, depression, and several personality disorders (A. J. Lewis et al., 2008; Milrod et al., 2007).

Next, we'll evaluate the current importance of psychoanalysis.

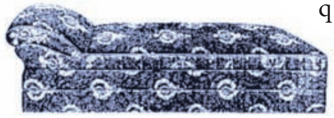
D. Long-Term Memory: Storing

Psychoanalysis: Evaluation



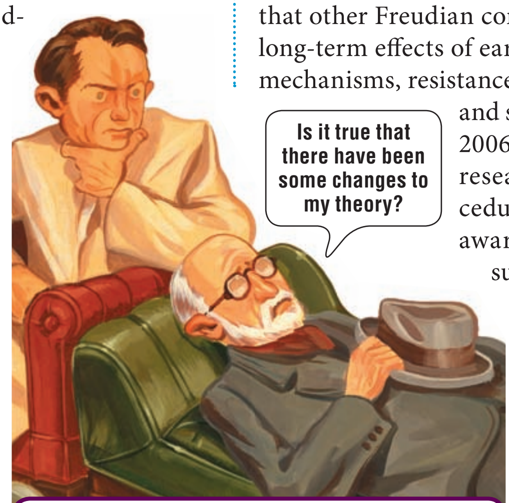
The 50th anniversary of Sigmund Freud's death (1939) was marked by a series of articles in *Psychoanalytic Quarterly* titled, "Is There a Future for American Psychoanalysis?" One author said that such a question was unheard of in the 1950s, when psychoanalysis was at the height of its popularity (Kirsner, 1990). However, after the 1950s, there was a decline in the popularity of psychoanalysis (Bornstein, 2001). Now, more than 150 years after Freud's birth (1856), many articles are reporting that some of his ideas are returning in popularity and describe his influence as an "inescapable force" (Adler, 2006). We'll discuss the decline in popularity of psychoanalysis following the 1950s as well as its current status.

Decline in Popularity

How did it happen that psychoanalysis, the number one therapy in the 1950s, lost its popularity and is now struggling to compete with other therapies? Here are some of the reasons according to its practitioners (Wallerstein & Fonagy, 1999; Westen & Gabbard, 1999).

■ **Lack of research.** In the 1970s, critics pointed out that almost no research had been done on whether the psychoanalytic process was an effective form of therapy. For example, psychoanalysts were very slow to analyze their own profession in terms of education—how best to train analysts—and to conduct research into what goes on during analysis and how to make it more effective. This criticism, which questioned the effectiveness of psychoanalysis, contributed to its decline in popularity.

■ **Competing therapies.** Perhaps the major reason for the decrease in popularity of psychoanalysis was that, beginning in the 1970s, a number of competing psychotherapies (discussed later in this module) were developed that proved to be equally effective but had a great advantage in that they are much quicker and far less costly. For example, psychoanalysis may require 200 to 600 sessions (2 to 4 per week for several years) versus about 25 for other therapies. This last point is particularly important, since most major health insurance plans limit either the amount of money or the number of sessions (usually about 25) for treatment of psychological problems. Because of this policy, health plans would not pay the costs of therapy for patients choosing psychoanalysis.



Is it true that there have been some changes to my theory?

Freud's method of psychoanalysis has declined in popularity, but his ideas have been incorporated into other therapies.

■ **Psychoactive drugs.** Another reason for the decline of psychoanalysis was the discovery of many new psychoactive drugs that proved effective in treating many of the problems formerly dealt with in psychoanalysis, such as anxiety and mood disorders. Some patients preferred drugs to psychoanalysis.

All of the above factors—lack of research on its effectiveness, development of new and less costly therapies, and discovery of psychoactive drugs—resulted in psychoanalysis experiencing a great decline from its peak popularity in the 1950s.

Current Status

Beginning in the 1980s and continuing to the present, there has been a major effort by psychoanalytic societies and their members to encourage research on the methods, concepts, and outcomes of therapy. This shift toward research indicates a major turning point in psychoanalysis. Previously, psychoanalysts almost exclusively reported individual case studies; they rarely studied the psychoanalytic process or its effectiveness using the experimental approach that had been adopted by competing therapies. For example, when researchers compared psychoanalysis with different kinds of long-term psychotherapies, they found that psychoanalysis was just as successful in improving patients' mental status (Blomberg et al., 2001). This is one example of the current efforts to test, compare, and show that long-term psychoanalysis can produce results as successful as those found with other therapies.

Freudian concepts. Current followers agree that some of Freud's concepts, such as the id being the source of energy, the importance of the Oedipus complex in personality development, and basic drives limited to sex and aggression, have proved difficult to verify. The same followers add that other Freudian concepts, such as the influence of unconscious forces, long-term effects of early childhood patterns, and the existence of defense mechanisms, resistance, and transference, have been experimentally tested and supported (Fotopoulou, 2006; L. Luborsky & Barrett, 2006; Ramachandran, 2006; Westen, 2007). For example, researchers discovered we have memories, called procedural or nondeclarative (p. 246), that are outside our awareness (unconscious) but affect various behaviors, such as acquiring strong emotional responses through classical conditioning (Mayes, 2000). Thus, two basic concepts underlying psychoanalysis—unconscious forces and defense mechanisms—have received support (Solms, 2006).

According to recent surveys, Freud's influence is very much alive in today's culture. Forty-three percent of adults in the United States believe dreams reflect unconscious desires, and nearly 30% believe that an adult's psychological problems can be traced back to his or her childhood (Adler, 2006).

Conclusion

Through the years, many ideas from Freud's classical psychoanalysis have been used to develop a kind of therapy called the psychodynamic approach. Although it shares some of its concepts with classical psychoanalysis, the psychodynamic approach has the therapist taking a more directive role that reduces the number of sessions but seems equally effective. One example of this newer approach is short-term dynamic psychotherapy (p. 562).

Next, we'll discuss an approach developed by a clinician who had been using Freud's psychoanalytic approach but became very displeased with it.

C. Insight Therapies

Client-Centered Therapy

What is a therapist's role?

As a therapist, Carl Rogers used the most popular therapy in his time, which was Freud's psychoanalytic approach. However, before long Rogers became dissatisfied with Freud's view that human nature was dependent on biological urges and instincts—sex and aggression—and that psychological problems arose from unconscious thoughts and desires that threatened one's self-concept. Rogers also disagreed with Freud's belief that the analyst—and not the client—was responsible for the client's progress. Instead, Rogers said that clients themselves have the capacity and are responsible for change. Using these ideas, Rogers developed client-centered therapy (C. R. Rogers, 1951, 1986).

Rogers believed that each person has a tendency to develop his or her potential.

Client-centered therapy (also called person-centered therapy) assumes that each person has an actualizing tendency, which is a tendency to develop one's full potential. The therapist's task is to be nondirective and show compassion and positive regard in helping the client reach his or her potential.

In client-centered therapy, Rogers changed the therapist's role from that of an all-knowing expert to a helper or facilitator, whose personal characteristics would foster growth and change (C. R. Rogers, 1986).

Therapy session. To illustrate some of the differences between psychoanalysis and client-centered therapy, here is a brief excerpt from a client-centered therapy session where a mother is talking about her problems with letting her daughter be more independent.

Client: I'm having a lot of problems dealing with my daughter. She's 20 years old; she's in college; I'm having a lot of trouble letting her go . . . And I have a lot of guilt feelings about her; I have a real need to hang on to her. And it's very hard with a lot of empty places now that she's not with me.

Rogers: The old vacuum, sort of, when she's not there.

Client: Yes, yes. I also would like to be the kind of mother that could be strong and say, you know, "go and have a good life," and it's really hard for me to do that.

Rogers: It's very hard to give up something that's been so precious in your life, but also something that I guess has caused you pain when you mentioned guilt.

Client: Yeah, and I'm aware that I have some anger toward her that I don't always get what I want. I have needs that are not met. And, uh, I don't feel I have a right to those needs. You know . . . she's a daughter; she's not my mother—though sometimes I feel as if I'd like her to mother me . . . It's very difficult for me to ask for that and have a right to it.

Rogers: So it may be unreasonable, but still, when she doesn't meet your needs, it makes you mad.

Client: Yeah. I get very angry, very angry with her. *(pause)*

Rogers: You're also feeling a little tension at this point, I guess.

Client: Yeah, yeah. A lot of conflict . . .

Rogers: A lot of pain.

Client: A lot of pain.

Rogers: A lot of pain. Can you say anything more what that's about? (adapted from C. R. Rogers, 1989).

Client-centered approach. In this brief excerpt, you can see two of the hallmarks of client-centered therapy. First, Rogers avoids giving any suggestions, advice, or disapproval and primarily shows the client that he understands what the client is feeling. Second, one technique Rogers uses for showing understanding is ***reflecting*** or restating the client's concerns. Reflecting the client's feelings is one of the basic techniques of the person-centered approach. In addition, humanistic therapists believe that clients have the capacity to discover and reach their true potential and it is the therapist's role to help and remove any roadblocks in their paths (Prochaska & Norcross, 2010).

Therapist's Traits

Rogers believed that personal characteristics of the therapist—empathy, positive regard, genuineness—would bring about the client's change. ***Empathy*** is the ability to understand what the client is saying and feeling. ***Positive regard*** is the ability to communicate caring, respect, and regard for the client. ***Genuineness*** is the ability to be real and nondefensive in interactions with the client. Rogers and his followers assumed that a therapist with these three characteristics would be able to help a client change and grow (Raskin et al., 2008).

However, numerous studies have shown that these three characteristics are not always related to successful outcomes (C. E. Hill & Nakayama, 2000). The success of client-centered therapy appears to be due more to developing a good working client–therapist partnership and to the client's attitudes of wanting to and working hard to change (Prochaska & Norcross, 2010).

What's blocking my path to developing my true potential?

Effectiveness

Client-centered therapy has been found to be effective in producing significant changes in clients in comparison with no-treatment control groups, but no more or less effective than other forms of therapy (C. E. Hill & Nakayama, 2000). According to client-centered therapy, the client–therapist relationship is the main reason the approach is effective (Kirschenbaum & Jourdan, 2005). Some studies, however, report that client-centered therapists who are very reflective and give very little direction are less effective than therapists who make more suggestions and give more direction (L. S. Greenberg & Rice, 1997).

Although very few therapists currently identify themselves as primarily client-centered in their approach, the principles of client-centered therapy have greatly contributed to making therapists aware of the importance of and the need to develop a positive working relationship with their clients (Kirschenbaum & Jourdan, 2005).

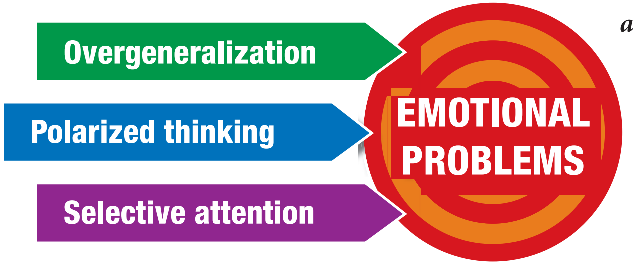
The therapist takes a much more directive role in the next kind of insight therapy, called cognitive therapy.

Figure/Text Credit: Therapy session adapted from "Person-Centered Therapy," by N. J. Raskin and C. R. Rogers, 1989. In R. J. Corsini and D. Wedding (Eds.), *Current Psychotherapies*, 4th ed. F. E. Peacock.

Cognitive Therapy

Do negative thoughts get you down?

Similar to Carl Rogers's experience, Aaron Beck was also trained in psychoanalytic techniques and used them to treat patients, many of whom were suffering from depression. When he asked them to free-associate, he noticed that depressed patients often expressed negative or distorted thoughts about themselves—"I'm a failure, no one likes me, nothing turns out right." What really caught his attention was how patients would express a string of negative thoughts almost automatically, without paying much attention. Beck reasoned that these automatically occurring negative thoughts had a great impact on the patients' lives, such as by lowering their self-esteem and encouraging self-blame and self-criticism. Beck developed his form of cognitive therapy to stop these thoughts and so treat depression and other problems (A. T. Beck, 1976, 1991).



Cognitive therapy, **as developed by Aaron Beck, assumes that we have automatic negative thoughts that we typically say to ourselves without much notice. By continually repeating these automatic negative thoughts, we color and distort how we perceive and interpret our world and influence how we behave and feel.**

Negative things we say to ourselves—for example, "Nothing ever goes right," "I'm a failure," or "Everybody criticizes me"—can bias and distort our thoughts and feelings. Cognitive therapy was developed to make a person aware of, and stop, negative self-statements.

Therapy session. To give you an idea of how negative thoughts occur, here is a brief excerpt from one of Dr. Beck's sessions.

The client is a 26-year-old graduate student who has bouts of depression.

Client: I get depressed when things go wrong. Like when I fail a test.

Therapist: How can failing a test make you depressed?

Client: Well, if I fail, I'll never get into law school.

Therapist: Do you agree that the way you interpret the results of the test will affect you? You might feel depressed, you might have trouble sleeping, not feel like eating, and you might even wonder if you should drop out of the course.

Client: I have been thinking that I wasn't going to make it. Yes, I agree.

Therapist: Now what did failing mean?

Client: *(tearful)* That I couldn't get into law school.

Therapist: And what does that mean to you?

Client: That I'm just not smart enough.

Therapist: Anything else?

Client: That I can never be happy.

Therapist: And how do these thoughts make you feel?

Client: Very unhappy.

Therapist: So it is the meaning of failing a test that makes you very unhappy. In fact, believing that you can never be happy is a powerful factor in producing unhappiness. So, you get yourself into a trap—by definition, failure to get into law school equals "I can never be happy" (A. T. Beck et al., 1979, pp. 145–146).

Why do I keep thinking all those negative thoughts?

Cognitive approach. Notice how the client tries to avoid admitting that her thoughts influence her feelings. Also notice her negative self-statements, such as "I'm just not smart enough" and "I can never be happy." Beck believes that these kinds of negative self-statements will influence this client's thoughts and feelings and contribute to her major symptom, depression.

Important Factors

Beck identified a number of specific maladaptive thoughts that contribute to various symptoms, such as anxiety and depression. Thus, thinking "I'm a failure" after doing poorly on one test is an example of ***overgeneralization,*** which is making blanket judgments about yourself on the basis of a single incident. Thinking "Most people don't like me" is an example of ***polarized thinking,*** which is sorting information into one of two categories, good or bad. Thinking "People always criticize me" is an example of ***selective attention,*** which is focusing on one detail so much that you do not notice other events, such as being complimented. Beck believes that maladaptive thought patterns cause a distorted view of oneself and one's world, which in turn may lead to various emotional problems. Thus, the primary goals of cognitive therapy are to identify and change maladaptive thoughts.

Cognitive techniques. Beck's approach, which is an example of cognitive therapy, works to change thought patterns, which, in turn, play a critical role in influencing behavior and emotions. In cognitive therapy, clients are told how their maladaptive thoughts and irrational beliefs can result in feelings of depression, anxiety, or other symptoms. Clients are shown how to monitor their thoughts and beliefs, how to recognize maladaptive thought patterns, such as overgeneralization and polarized thinking, and how to substitute rational thought patterns (A. T. Beck & Weishaar, 2008). In the Application section (p. 574), we'll give several examples of specific techniques for stopping negative thoughts and substituting positive ones.

Effectiveness

Cognitive therapy has proved effective in treating a variety of symptoms. For example, it is as effective as various drugs in treating depression, bipolar disorder, general anxiety, social phobia, agoraphobia, panic attacks, smoking, anger, and eating disorders. The benefits of cognitive therapy extend beyond the end of treatment. In some cases, the benefits last longer than those of other forms of therapy (Ball et al., 2006; Clark et al., 2006; DeRubeis et al., 2005; Dobson & Khatri, 2000; Rupke et al., 2006).

Increasingly, methods of cognitive therapy are combined with those of the next approach, behavior therapy. The result is a very popular approach called cognitive-behavioral therapy. However, before explaining cognitive-behavioral therapy, we'll need to discuss behavior therapy, which is our next topic.

Figure/Text Credit: Therapy session adapted from *Cognitive Therapy of Depression*, by A. T. Beck, A. J. Rush, B. F. Shaw & G. Emery, 1979, pp. 145–146. Guilford Press.

D. Behavior Therapy

Definition

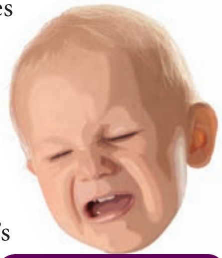
What's so important about Little Albert?

The 1950s was the time Carl Rogers developed client-centered therapy and Aaron Beck developed cognitive therapy. Both were motivated to develop new approaches because they had become disillusioned with the techniques and results of the psychoanalytic approach, which they had used in clinical practice.

This was also the time Joseph Wolpe (1958, 1990), a physician in South Africa, became disillusioned with psychoanalysis and developed a new, quicker, and more effective procedure to reduce fear and anxiety.

Through classical conditioning, this pet rat . . .

At the beginning of this module, we told you about Little Albert, who initially wanted to touch and play with a white rat but, after being conditioned, came to fear it (Watson & Rayner, 1920). This demonstration, which occurred in the 1920s, showed that emotional responses could be conditioned. But it was not until the 1950s that a clinician developed a procedure to unlearn emotional responses.



. . . came to be feared by Little Albert.

In a real sense, Wolpe finished what John Watson had started: Watson had conditioned Little Albert to fear an object, while Wolpe conditioned patients to be less fearful. Wolpe's procedure was the first experimental demonstration of reducing fear through conditioning and gave a real jump-start to the development of behavior therapy (Persons, 1997).

Behavior therapy, **also called behavior modification, uses the principles of classical and operant conditioning to change disruptive behaviors and improve human functioning. It focuses on changing particular behaviors rather than the underlying mental events or possible unconscious factors.**

We'll first give you an example of a behavior therapy session and then describe Wolpe's conditioning procedure to reduce fear.

Therapy session. In this session, the therapist is talking to a woman who feels bad because she has great difficulty being assertive.

Client: The basic problem is that I have the tendency to let people step all over me. I don't know why, but I just have difficulty in speaking my mind.

Therapist: So you find yourself in a number of different situations where you don't respond the way you would really like to and you would like to learn how to behave differently.

Client: Yes. But you know, I have tried to handle certain situations differently, but I just don't seem to be able to do so.

Therapist: Well, maybe you tried to do too much or didn't quite know the right technique. For example, imagine yourself at the bottom of a staircase, wanting to get to the top. It's too much to ask to get there in one gigantic leap. Perhaps a better way to go about changing your reaction in these situations is to take it one step at a time.

Client: That would seem to make sense, but I'm not sure if I see how it could be done.

PowerStudy 4.5™

Module 9
F. Research Focus: Conditioning Little Albert
Module 10
I. Application: Behavior Modification

Therapist: Well, there are probably certain situations in which it would be less difficult for you to assert yourself, such as telling your boss that he forgot to pay you for the past four weeks.

Client: *(laughing)* I guess in that situation, I would say something. Although I must admit, I would feel uneasy about it.

Therapist: But not as uneasy as if you went in and asked him for a raise.

Client: No. Certainly not.

Therapist: So, the first situation would be low on the staircase, whereas the second would be higher up. If you can learn to handle easier situations, then the more difficult ones would present less of a problem. And the only way you can really learn to change your reactions is through practice.

Client: In other words, I really have to go out and actually force myself to speak up more, but taking it a little bit at a time?

Therapist: Exactly. And it's easier and safer to run through some of these situations here because you can't really get into trouble if you make a mistake. Once you learn different ways to speak your mind, you can try them out in the real world (adapted from Goldfried & Davison, 1976).

Behavioral approach. Notice that the behavior therapist does not encourage the client to free-associate, which is a major technique of psychoanalysis. The behavior therapist does not repeat or reflect what the client says, which is a major technique of client-centered therapy. The behavior therapist does not discuss the client's tendency to automatically think negative thoughts, which is a major technique of cognitive therapy.

Instead, the behavior therapist quickly identifies the specific problem, which is the woman's tendency to be unassertive when she really wants to speak her mind. Next, the behavior therapist will discuss a program for behavioral change that will help this woman learn to behave more assertively.

Two goals. Behavior therapy has two goals. The first is to modify undesirable behaviors, using many of the principles of operant conditioning, and teach the client how to perform new behaviors, which for this woman involves learning ways to be more assertive. The second goal of behavior therapy is to help the client meet specific behavioral goals through constant practice and reward (Spiegler & Guevremont, 2009). For example, this woman would be asked to practice initiating conversations and stating her opinions, perhaps beginning in the safety of the therapist's office and gradually practicing these new assertive behaviors in the more threatening situations of the real world.

Why do I let people walk all over me?

The next example of behavior therapy illustrates a specific technique that is used to help clients overcome phobias.

Systematic Desensitization

Case Study

Jack had developed a phobia of blood that interfered with his plans. He was a high-school senior who wanted to be an ambulance driver. But the problem was that he passed out at the sight or discussion of blood. He had been afraid of blood for years and had fainted about 20 times in science and biology classes. He even felt queasy when bloody accidents or operating-room scenes were shown on television. If his supervisor found out about his phobia, Jack might lose his chance to be an ambulance driver. Except for his phobia, Jack was happy at school, rarely became depressed, and was generally easygoing (Yule & Fernando, 1980).

Jack's fear of blood interfered with his being an ambulance driver.

Some therapies for phobias might require years of treatment; for instance, a psychoanalyst would search for unconscious conflicts causing the phobia. In contrast, behavior therapists would take a direct approach to the treatment, requiring 5 to 30 sessions. The technique used today by behavior therapists is based on the one that Wolpe (1958) developed in the 1950s and is called systematic desensitization.

Systematic desensitization **is a technique of behavior therapy in which the client is gradually exposed to the feared object while simultaneously practicing relaxation. Desensitization involves three steps: learning to relax, constructing a hierarchy with the least feared situation on the bottom and the most feared situation at the top, and being progressively exposed to the feared situation.**

Behavior therapists assume that since Jack's phobia was acquired through a conditioning process, his phobia can be unconditioned by gradually exposing him to the feared object through the process of systematic desensitization.

1 Relaxation

Jack, whose phobia was a fear of blood, underwent systematic desensitization, a very effective treatment for phobias (Cormier & Nurius, 2003). In the first step, Jack learned to relax by practicing progressive relaxation. This method involves tensing and relaxing various muscle groups, beginning with the toes and working up to the head. With this procedure, Jack learned how to put himself into a relaxed state. For most individuals, learning progressive relaxation requires several weeks with at least one 15-minute session every day.

2 Stimulus Hierarchy

The second step was for Jack to make a ***stimulus hierarchy,*** which is a list of feared stimuli, arranged in order from least to most feared. With the help of his therapist, Jack made the stimulus hierarchy shown on the right, which lists various situations associated with blood. A rating of 1 indicates little fear if confronted by this stimulus, while a rating of 7 indicates that Jack would probably pass out from this stimulus.

MOST STRESSFUL

7 Needle drawing blood
6 Finger dripping blood
5 Seeing someone cut
4 Needle entering arm
3 Watching blood on TV
2 Cutting own finger
1 Seeing word "blood"

Stimulus hierarchy ranks fearful situations from least (1) to most (7).

3 Exposure

Systematic desensitization training means that, after successfully completing steps 1 and 2, Jack was ready for step 3, which was to systematically desensitize himself by exposing himself to the fear stimuli. Desensitization occurs through relaxing while simultaneously imagining the feared stimuli.

Jack put himself into a relaxed state and then imagined the first or least feared item in his hierarchy, seeing the word ***blood.*** He tried to remain in a relaxed state while vividly imagining the word ***blood.*** He repeated this procedure until he felt no tension or anxiety in this situation. At this point, he went on to the next item in his hierarchy. Jack repeated the procedure of pairing relaxation with images of each feared item until he reached the last and most feared item.

Through the desensitization program described here, Jack's blood phobia was treated in five one-hour sessions. A follow-up five years later indicated that Jack was still free of his blood phobia, had not developed any substitute symptoms, and was training to be an ambulance driver (Yule & Fernando, 1980).

A necessary part of therapy is exposure to the feared situation.

Exposure: Imagined or In Vivo

Systematic desensitization appears to be most effective if, instead of just imagining the items on the list, which is called ***imagined exposure,*** clients gradually expose themselves to the actual situation, which is called ***in vivo exposure*** (the phrase *in vivo* is Latin for "in real life") (G. T. Wilson, 2005). For example, in Module 22 we described the case of Kate Premo (right photo), who signed up for a treatment course that used in vivo exposure to treat her lifetime phobia of flying. In her case, a modified systematic desensitization program included in vivo exposure, which meant taking an actual flight while doing the breathing and relaxation exercises that she had learned. The in vivo exposure worked for Premo, who was able to overcome her phobia of flying.

Systematic desensitization has proved to be a very effective treatment for a variety of anxiety disorders, especially when combined with in vivo exposure (Moscovitch et al., 2008). Later, in the Critical Thinking section (p. 578), we'll discuss how systematic desensitization is being used in virtual therapy, a revolutionary new treatment approach.

The next therapy is actually a combination of behavior and cognitive therapies.

Kate is being exposed to the actual situation (in vivo) that causes her fear, flying in an airplane.

D. Behavior Therapy

Cognitive-Behavioral Therapy

Why combine two different therapies?

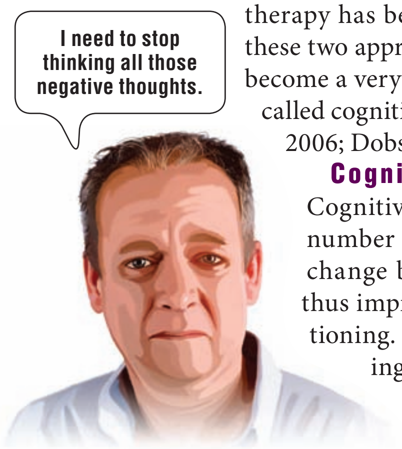
As psychoanalysis reached its peak of popularity in the 1950s, a number of clinicians and researchers were becoming dissatisfied with its procedures, which were time-consuming, costly, and useful for treating only a limited number of clients with relatively minor problems (Franks, 1994).

At this same time, there was a great increase in the popularity of learning principles that came from Pavlov's work on classical conditioning and Skinner's work on operant conditioning. Researchers and clinicians began to apply these learning principles to change human behavior with methods based on a strong experimental foundation rather than Freud's unverified beliefs about unconscious conflicts. Both behavior and cognitive therapies developed out of dissatisfaction with psychoanalysis and the belief that learning principles would provide more effective methods of changing human behavior than would the concepts of psychoanalysis.

Combining therapies. One of the interesting developments in therapy has been occurring since the late 1970s as both behavior and cognitive therapies have become increasingly popular. The major difference between them is that ***behavior therapy*** focuses on identifying and changing specific behaviors, while ***cognitive therapy*** focuses on identifying and changing specific maladaptive thought patterns. Beginning in the early 1990s, researchers and clinicians began combining the methods of behavior and cognitive therapies into what is now called cognitive-behavioral therapy (P. Grant et al., 2005).

Cognitive-behavioral therapy combines the cognitive therapy technique of changing negative, unhealthy, or distorted thought patterns with the behavior therapy technique of changing maladaptive or disruptive behaviors by learning and practicing new skills to improve functioning.

Currently, the difference between cognitive therapy and behavior therapy has become blurred as techniques from these two approaches are combined into what has become a very popular therapy that is commonly called cognitive-behavioral therapy (Butler et al., 2006; Dobson, 2009).



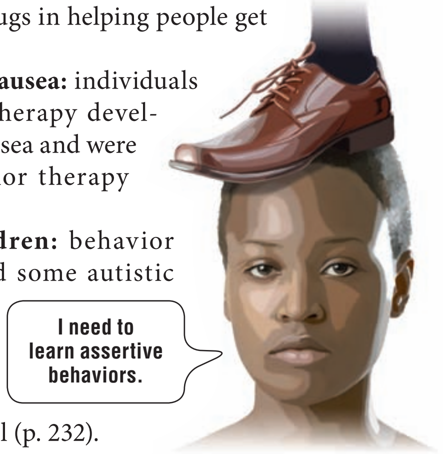
I need to stop thinking all those negative thoughts.

Cognitive-behavioral techniques. Cognitive-behavioral therapists combine a number of techniques that are designed to change both thoughts and behaviors and thus improve a person's psychological functioning. These techniques include monitoring one's own thoughts and behaviors; identifying thoughts and behaviors that need to be changed; setting specific goals that increase in difficulty; learning to reinforce oneself for reaching a goal; imitating or modeling new behaviors; substituting positive for negative thoughts; and doing homework, which involves practicing new behaviors in a safe setting before performing them in the real world (A. T. Beck & Weishaar, 2008). These cognitive-behavioral techniques are the basis for almost all ***self-help programs,*** which may be completed without the assistance of a therapist. For more serious problems or additional support, the aid and help of a therapist may be needed.

Kinds of Problems

Who can be helped?

Throughout this text, we have discussed how behavior therapy, cognitive therapy, and the popular cognitive-behavioral therapy have been used to treat the following problems:



I need to learn assertive behaviors.

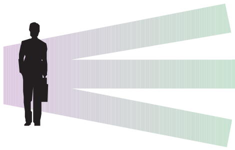
- **Insomnia:** cognitive-behavioral program was as effective as drugs in helping people get to sleep (p. 162).
- **Conditioned nausea:** individuals undergoing chemotherapy developed conditioned nausea and were treated with behavior therapy (p. 207).
- **Autistic children:** behavior modification helped some autistic children develop sufficient academic and social skills to enter public schools and function very well (p. 232).
- **Psychosomatic problems:** behavior therapy (biofeedback) helped people decrease stress-related symptoms by reducing headaches and physiological arousal (p. 233).
- **Abusive parents:** cognitive-behavioral therapy that involved training in social skills helped parents deal with their own personal problems as well as daily difficulties related to caring for demanding children (p. 401).
- **Stress management:** cognitive-behavioral techniques are basic to all programs for reducing stress (p. 502).
- **Phobias:** various phobias, such as fear of specific situations (flying, public speaking) or objects (snakes, bugs, blood), were treated with cognitive-behavioral techniques (pp. 225, 524, 525).

We'll also discuss several other examples of cognitive-behavioral techniques in the Application section.

Effectiveness. Cognitive-behavioral therapy is currently being used to treat a wide variety of problems, including eating disorders, marital problems, anxiety and phobias, depression, and sexual dysfunction. Programs based on cognitive-behavioral therapy are widely used to help people stop smoking, become more assertive, improve communication and interpersonal skills, manage stress, and control anger. Researchers report that cognitive-behavioral therapy was significantly more effective in treating this wide variety of problems than were control procedures (Butler et al., 2006; Dobson, 2009). And in some cases, cognitive-behavioral therapy was as effective as drugs in treating some forms of anxiety, phobia, depression, and compulsive behavior (Butler et al., 2006; Spiegler & Guevremont, 2009).

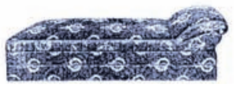
After the Concept Review, we'll review and compare the development, techniques, and effectiveness of all the major therapies that we have discussed.

Concept Review



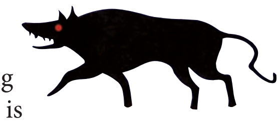
1. If you first trained as a physician and then went into a psychiatric residency, which involves additional training in pharmacology, neurology, and psychotherapeutic techniques, you would be a (a) ______________. If you completed a PhD program in psychology, including one year of work in a clinical setting, you would be a (b) ______________. If you completed a PhD program in psychology or education, including work in a counseling setting, you would be a (c) ______________.

2. A process characterized by verbal interaction between therapist and client and the development of a supportive relationship, during which a therapist may analyze or suggest ways for the client to deal with and overcome his or her problems, is called ______________.



3. One approach to therapy is characterized by the idea that we have an unconscious part whose activities and thoughts are hidden behind a mental barrier that we cannot voluntarily remove. Behind this barrier are repressed and psychologically dangerous thoughts that give rise to unconscious conflicts, which, in turn, can result in psychological and physical symptoms. This approach is called ______________.

4. Freud developed two techniques to uncover unconscious thoughts. One was to encourage clients to talk about any thoughts or images that entered their heads, which is called (a) ______________. The second technique was based on the assumption that dreams contain hidden meanings and symbols and the therapist's role was to (b) ______________ these dream symbols.

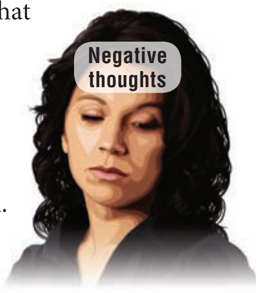


5. Freud said that, during therapy, a patient may respond as if the therapist were a father or mother and project strong feelings toward the therapist. This process is called (a) ______________. Also during therapy, a patient may be reluctant to work through feelings or to recognize unconscious conflicts and repressed thoughts; this is called (b) ______________.

Psychoanalysis

6. The popular approach to therapy shares many of the features of psychoanalysis—for example, discussing the client's feelings, breaking down the client's defenses and resistances, and interpreting the client's behaviors—but may not necessarily use free association or agree that many problems result from unconscious sexual conflicts. This approach, which takes less time than psychoanalysis, is called ______________ psychotherapy.

7. One approach to therapy assumes that each person has an actualizing tendency—that is, a tendency to develop his or her full potential. In this approach, the therapist's task is to show compassion and positive regard in helping the client reach his or her potential. This approach was developed by (a) ______________ and is called (b) ______________ therapy.



8. Another approach to therapy assumes that we have automatic negative thoughts that we usually say to ourselves without much notice. By continually repeating these automatic negative thoughts, we color and distort how we perceive and interpret our world and influence how we behave and feel. This approach to therapy was developed by (a) ______________ and is called (b) ______________ therapy.

9. One approach to therapy primarily uses the principles of classical and operant conditioning to change disruptive behaviors and improve human functioning. This approach, which focuses on changing particular behaviors rather than on the underlying mental events or possible unconscious factors, is called ______________ therapy.

10. One approach combines changing negative, unhealthy, or distorted thoughts and beliefs by substituting positive, healthy, and realistic ones and changing one's undesirable or disruptive behaviors by learning and practicing new skills to improve functioning. This approach, which combines two therapies, is called ______________ therapy.

11. There is a technique of behavior therapy in which the client is gradually exposed to the feared object while simultaneously practicing relaxation. This technique, which involves three steps—learning to relax, constructing a hierarchy with the least feared situation on the bottom and the most feared situation at the top, and being progressively exposed to the feared situation—is called ______________.

12. Because of its effectiveness, cognitive-behavioral therapy has become the basis for many self-help programs to stop smoking, reduce insomnia, decrease conditioned nausea, help autistic children develop academic and social skills, and reduce intense and irrational fears called ______________.

Answers: *1. (a) psychiatrist, (b) clinical psychologist, (c) counseling psychologist; 2. psychotherapy; 3. psychoanalysis; 4. (a) free association, (b) interpret; 5. (a) transference, (b) resistance; 6. psychodynamic; 7. (a) Carl Rogers, (b) client-centered; 8. (a) Aaron Beck, (b) cognitive; 9. behavior; 10. cognitive-behavioral; 11. systematic desensitization; 12. phobias*

E. Review: Evaluation of Approaches

Background, Assumptions, and Techniques

How do they differ?

We have discussed five different approaches to psychotherapy, including psychoanalysis, client-centered therapy, cognitive therapy, behavior therapy, and the increasingly popular cognitive-behavioral therapy. We'll briefly review the different backgrounds, assumptions, and techniques for four of these approaches, and then discuss their effectiveness.

Psychoanalysis

Psychoanalysis

Background. Psychoanalysis, which was developed by Sigmund Freud in the late 1800s and early 1900s, marked the beginning of psychotherapy. Freud gradually developed his major assumptions from treating patients for a variety of symptoms and problems. Thus, Freud's assumptions are based on case studies rather than on experimental data.

Basic assumption. Freud believed that unacceptable or threatening thoughts were repressed and unavailable to conscious recall. Repressed thoughts could produce unconscious conflicts that, in turn, could result in feelings of anxiety and a variety of psychological and emotional problems.

Techniques. Freud developed two techniques for uncovering and revealing unconscious thoughts: free association and dream interpretation. Freud was also the first to identify and recognize the importance of transference and resistance during therapy. He believed that patients overcame their problems by bringing up and dealing with underlying unconscious conflicts.

Client-Centered Therapy

Background. In the late 1940s and early 1950s, Carl Rogers became disillusioned with the psychoanalytic role of the therapist as expert and in charge of changing the client. To give the client a greater role in making decisions and changes, he developed his client-centered approach.

Basic assumption. Rogers assumed that the client has the capacity to actualize and reach his or her full potential and the client, not the therapist, is responsible for change. He believed that, although the client had the major role in making changes, there were certain characteristics of the therapist that helped the client change.

Techniques. The client-centered therapist uses the technique of repeating or reflecting what the client says and thereby showing interest and understanding. Rogers believed that therapists would be effective if they had three characteristics: empathy, positive regard, and genuineness. These characteristics produced a warm and supportive atmosphere in which the client felt comfortable and could better deal with solving his or her problems.

Cognitive Therapy

Background. In the late 1960s and early 1970s, Aaron Beck became dissatisfied with the psychoanalytic assumption that unconscious conflicts were the chief cause of psychological problems. As Beck treated patients, he noticed that they would often repeat a string of negative statements, almost without notice. Beck believed that these automatic, negative self-statements played a major role in emotional problems.

Basic assumption. Beck pointed out that our automatic, irrational thoughts and beliefs can color our feelings and actions, distort our perceptions, and result in various psychological and emotional problems. He assumed that these irrational self-statements, such as polarized thinking, needed to be changed.

Techniques. The techniques of cognitive therapy include having the client monitor and identify his or her automatic, negative, irrational thoughts and replace them with positive ones. Thus, clients deal with and solve their problems by gradually substituting positive thoughts for distorted self-statements.

Behavior Therapy

Background. Developed in the 1950s, behavior therapy was based on principles of learning from classical and operant conditioning. Behavior therapy was a reaction against psychoanalysis, whose emphasis was on unconscious and unobservable conflicts and whose concepts lacked a scientific foundation.

Basic assumption. Behavior therapy assumes that just as emotional reactions can be learned or conditioned, so too can they be unlearned using the same principles of learning. Behavior therapy focuses on observable behaviors, while cognitive-behavioral therapy also emphasizes changing thought patterns.

Techniques. The behavior therapist identifies specific behaviors that need to be changed and provides the client with particular methods for carrying out the changes. Specific behavioral techniques include self-observation, self-reward, modeling, and role playing. For treatment of anxiety, fears, and phobias, systematic desensitization combined with in vivo exposure has proved effective.

Currently, techniques of cognitive and behavior therapies are combined into ***cognitive-behavioral therapy,*** which has proved effective for treating a variety of psychological problems and self-help programs.

Because these four approaches differ in their assumptions and techniques, is one approach more effective than another?

Effectiveness of Psychotherapy

How helpful is psychotherapy?

Nearly 20% of the adult population in the United States seek help and treatment for mental illness from various mental services (Adler, 2006). However, about half of all individuals who have a serious mental health problem do not seek treatment because they want to avoid the stigma that many in our society attach to mental illness (Satcher, 2000). Mental health professionals have tried to erase this stigma by explaining that mental illness is not a character flaw but a real health problem that can often be successfully treated with therapy programs that may involve drug, nondrug, or a combination of therapies.

A person needs therapy for a problem if that problem begins to interfere with the person's social interactions, relationships, work, career, or daily functioning.

How do I know if I need therapy for my problem?

Researchers have analyzed over 1,500 studies that examined the effects of psychotherapy on a variety of problems, such as depression, various kinds of anxieties, family problems, interpersonal difficulties, and eating disorders. Researchers found that psychotherapy was more effective in relieving a wide variety of psychological and behavioral symptoms than were control procedures such as being on a waiting list to receive therapy or just being in a group that received no systematic treatment.

Knowing that psychotherapy is an effective treatment brings us to the second question: Is one kind of psychotherapy more effective than another?

Common Factors

Is one approach more effective?

If you lived fifty years ago and needed professional help for a mental illness, your only choice was psychoanalysis, which was very time-consuming and expensive. In contrast, if you need professional help today, you can choose from a number of different therapies, which are available at a variety of mental health facilities. However, because the current therapy approaches begin with different assumptions and use different methods, you might wonder if one therapy is more effective than another. In answer to this question, researchers have consistently found that there is very little, if any, difference in effectiveness among various therapies (Drisko, 2004; L. Luborsky et al., 2002). However, for a small number of specific disorders, including ***panic attacks, phobias, generalized anxiety, obsessive-compulsions, insomnia,*** and ***depression,*** cognitive-behavioral-type therapies have generally been shown to be more effective than traditional talk therapies, such as the psychodynamic approaches (Butler et al., 2006; Dobson & Khatri, 2000).

It may seem surprising that therapies with such different assumptions and techniques have been found to be equally effective. One reason different therapies using different techniques achieve the same results is they all share common factors (L. Luborsky et al., 2002).

Common factors are a basic set of procedures and experiences that different therapies share and that explain why different approaches are equally effective. Common factors include the growth of a supportive and trusting relationship between therapist and client and the development of an accepting atmosphere, in which the client feels willing to admit problems and is motivated to work on changing.

The fact that the above common factors are basic to all approaches explains why different assumptions and different techniques can be effectively combined to develop the several different current forms of psychotherapy, all of which are about equally effective (L. Luborsky et al., 2002).

Related to the common factors of various therapeutic approaches is the basic assumption that therapy takes places face to face, with therapist and client in the same room. In this regard, you may find the recent growth in cybertherapy, discussed next, a bit surprising.

I found out that many of the therapies are about equally effective.

Cybertherapy

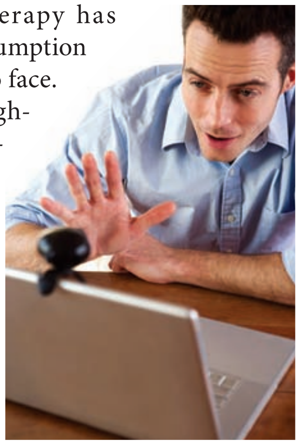
Is cybertherapy really therapy?

Our understanding of therapy has largely been based on the assumption that it must take place face to face. However, cybertherapy, a high-tech way to deliver therapeutic services, challenges this basic assumption.

Cybertherapy is therapy delivered over the Internet.

Cybertherapy can range from clients e-mailing questions or concerns to a therapist, who in turn responds by e-mail, to clients sitting in front of a camera mounted on their computer and having a live online session with a therapist (right photo).

The advantages of cybertherapy are that it reduces costs and improves access to therapeutic services in areas with limited availability of mental health services. The disadvantages are that cybertherapists may not have the same credentials and are generally not as well trained as traditional therapists. Also, cybertherapists cannot clearly see body gestures or facial expressions and cannot clearly hear the emotional tone in a client's voice.



Initial research on cybertherapy suggests it has promise; however, more controlled experimental research is needed to better assess its effectiveness (Barak et al., 2008; Derrig-Palumbo & Zeine, 2005; Rochlen et al., 2004; Zack et al., 2004).

Cybertherapy may seem strange to some, but the next treatment feels very strange to most Westerners.

F. Cultural Diversity: Different Healer

Case Study: Young Woman

What was her problem?

In Bali, which is a province of Indonesia, as well as in parts of Africa, China, and Fiji Islands, many psychological problems that Western clinicians would diagnose as anxiety, mood disorders, or schizophrenia are believed to be caused by possession by evil spirits (Hobart, 2003; McGrath, 2003). For example, take the case of Putu, a young unmarried woman, who was about 20 years old.

Putu lived with her family in a small village on the beautiful island of Bali. Putu's family had made her break off her loving relationship with one man and become engaged to another, whom she did not want to marry. Since her new engagement, Putu had lost all interest in things around her, ate very little, and did not take part in normal activities or conversation. Putu was taken to the local nurse, who gave an injection of multivitamins to treat her low energy level and general apathy. The injection did not help and the nurse recommended that the family take Putu to a local witch doctor or healer, who could use special rituals to cure Putu (L. Connor, 1982).

In Western terminology, clinicians would say that Putu was suffering from depression, which was most certainly brought on by having to break off her loving relationship and being forced by her family to become engaged to someone she did not like. Western therapists would have treated her depression with some form of psychotherapy and, if possible, would have brought the whole family in for therapy. However, in Bali, Putu was believed to be the victim of witchcraft, which could be cured by taking her to a traditional healer, who is called a *balian*.

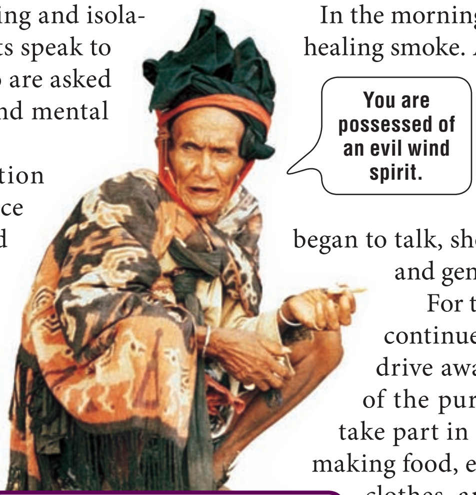
Healer's Diagnosis and Treatment

What is healing smoke?

The family took the depressed Putu to a well-respected healer, or balian, a woman named Jero. Balians, such as Jero, believe their powers come from supernatural forces. The balians often undergo periods of fasting and isolation that induce trances through which the spirits speak to them. Balians are considered special healers who are asked to help individuals with a variety of personal and mental problems (Keeney, 2004).

In Putu's case, Jero located a small pulsation beneath Putu's jawbone that indicated the presence of an evil wind spirit. The rejected lover had placed the evil spirit into Putu's body, and there was now a great danger that this evil spirit might travel throughout her body: If it reached Putu's ears, she would go deaf; if it reached her brain, she would become violent and insane. Jero (right photo) said that she would mix a special medicine and that the family should return in two days for an exorcism of the evil wind spirit.

As part of the exorcism rites, two small human effigies, a male and a female, were made out of cooked rice and were set on the ground to the south of the girl. When the evil spirit was driven out of Putu's body by smoke, the evil spirit would be attracted to the effigies, which would then be broken to destroy the spirit.



You are possessed of an evil wind spirit.

Indonesian healers, called balians, function like Western therapists.

In the morning, Jero asked Putu to stand in the middle of healing smoke. After about 40 minutes, the evil wind spirit left Putu's body and entered the small male and female rice figures, which were broken and thrown away. Then Putu's body was purified with holy water. During the course of the afternoon, Putu began to talk, show interest in food and things around her, and generally get over her former apathy.

For two more weeks, Putu stayed with Jero, who continued to perform purification ceremonies and drive away any lingering evil wind spirits. As part of the purification ceremonies, Putu was asked to take part in everyday activities, such as gathering and making food, engaging in normal conversations, washing clothes, and doing other chores. Through this process, Putu was helped and encouraged to resume her normal duties and take part in social activities.

Healers Versus Western Therapists

Is a balian a therapist?

The case of Putu shows that the beliefs and treatments used in the traditional healing practices of African and Asian balians or healers are very different from those used by Western therapists to treat psychological problems. But notice that the balian's exorcism rites, purification rituals, and herbal medicines did reduce Putu's depression. In many parts of Asia, China, Africa, Fiji Islands, and Indonesia, healers use herbal medicines, exorcism, and purification rituals to successfully treat a variety of psychological problems (McGrath, 2003; Sue & Sue, 2007).

There are two explanations of why a balian's potions and rituals are effective treatments for various mental and physical problems. First, studies on Western patients find that many patients suffering from a variety of psychological and physical problems show remarkable improvement after receiving placebo treatments (Wampold et al., 2005). The balian's rituals and herbs may function like Western placebos (p. 111), which create positive beliefs and expectations to help individuals recover from a variety of physical and psychological problems. Second, the balian's purification ceremonies involve the development of a close relationship with the sufferer, and this relationship may involve common factors similar to those found effective in Western therapy. Thus, placebos and psychotherapy's common factors may explain the success of balians in treating a variety of mental problems in different cultures.

Next, we'll discuss treatment of one of the more difficult psychological problems, getting over a terrible and traumatic situation.

G. Research Focus: EMDR—New Therapy

Does EMDR Stop Traumatic Memories?

What is EMDR?

In the early 1990s a new kind of psychotherapy appeared that was unlike any we have discussed. After only a few sessions, clients reported a decrease in traumatic memories, a problem very difficult to treat. This therapy was called Eye Movement Desensitization and Reprocessing (F. Shapiro, 2002).

Eye Movement Desensitization and Reprocessing, **or** ***EMDR,*** **essentially involves having the client talk about or imagine a troubling traumatic memory while visually focusing on and following the back-and-forth movement of a therapist's hand. This process usually continues for several 90-minute sessions, after which the traumatic memories are greatly reduced or eliminated.**

Can watching a moving hand reduce terrible memories?

Francine Shapiro (1991) discovered EMDR after noticing that her own troubling thoughts disappeared after she associated them with her back-and-forth eye movements. Because EMDR's method and claims were so unusual, researchers wondered if it really worked.

Evidence from Case Studies

All of the early support for the effectiveness of EMDR came from testimonials and case studies, many of them as dramatic as the following:

After one individual lost both arms and hearing in a tragic fire and explosion, he experienced terrible flashbacks and nightmares for the next six years. When he finally consulted a psychiatrist, he was desperate and agreed to try the then-new EMDR procedure. During the EMDR procedure, he vividly recalled the fire, the shouts of the employees, and other terrible images, while visually following the back-and-forth movement of the therapist's hand. However, as he continued imagining terrible images and following the therapist's hand movements, he began to feel a flowing sensation of peace. Following a number of sessions, he was reported to be free of flashbacks and nightmares, had taught himself to drive a car, and had joined a group that helps children who need artificial limbs (Wartik, 1994).

Dramatic cases like this suggested that EMDR was a very simple yet effective treatment for getting rid of traumatic memories, one of the most difficult problems therapists face. In explaining how EMDR worked, Shapiro (1991) hypothesized that the eye movements during EMDR aided information processing to somehow reduce the distress accompanying traumatic events and images.

During EMDR, a client talks about a painful memory while watching a therapist's moving hand.

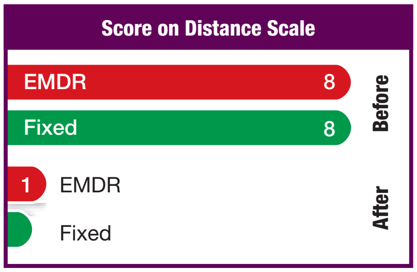
Photo Credit: © *Los Angeles Times*, photo by Al Seib

Although the effectiveness of EMDR was supported by case studies and testimonials, we must remember that such methods have great potential for error and bias and cannot demonstrate cause and effect. Thus, to evaluate the effectiveness of EMDR, researchers used a more scientific approach, the experimental method (p. 36).

Evidence from Experiments

Does EMDR work? We have discussed many examples of so-called "medical treatments" (Korean centipedes, rhino horns, fake pills and injections) that, according to 30–80% of users' testimonials, reduced pain, increased sexual stamina, or cured various physical problems (pp. 31, 111) (Talbot, 2000). These "medical treatments" are examples of the well-known ***placebo effect,*** which can have a powerful influence and may explain why EMDR works. For nearly 20 years, researchers have studied EMDR therapy and generally concluded that it was not simply a placebo effect but was effective in reducing traumatic memories, such as occur in posttraumatic stress disorder or PTSD (p. 491). So our first question, Does EMDR work? has been answered positively (R. Shapiro, 2005; S. M. Silver et al., 2005).

However, wondering if eye movement was the critical feature of EMDR therapy, researchers compared clients who moved their eyes with those who stared straight ahead. As shown in the right graph, subjects who made eye movements (EMDR) and who fixed their stare both showed significant reductions in distress (Renfrey & Spates, 1994). Researchers now know that different kinds of stimulation (eye movements, fixed staring, hand taps) are effective as long as such stimulation occurs while clients are recalling their traumatic memories (May, 2005; F. Shapiro & Maxfield, 2002).



How does EMDR work? This question has not yet been answered. What is known is that, during EMDR, clients are recalling and confronting their most feared feelings, images, or situations, an established method of exposure therapy (p. 567). Thus, many researchers suggest that EMDR may be another form of traditional exposure therapy, which is very effective for reducing fearful thoughts, images, and situations (Lilienfeld & Arkowitz, 2006). However, others suggest the treatment process of EMDR is unique because the eye movements allow patients to emotionally distance themselves from the trauma experiences (C. W. Lee et al., 2006). At this point there are three therapies—EMDR, exposure therapy, and cognitive-behavioral therapy (p. 568)—that have been shown to be effective treatments for posttraumatic stress disorder (F. Shapiro, 2002).

Why is EMDR controversial? Some of the reasons EMDR has been so controversial are that it seems too unusual, too simple, and too quick. However, research has shown that EMDR is one of three therapies that is effective for treating a notoriously difficult and unusually persistent problem—the occurrence of traumatic memories (Marsa, 2002; R. Shapiro, 2005).

Next, we'll review several cognitive-behavioral techniques.

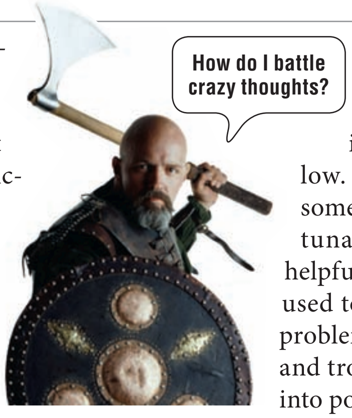
H. Application: Cognitive-Behavioral Techniques

Thought Problems

What's a common problem?

There are a number of psychological/behavioral problems that are not usually considered serious mental disorders but that can be very bothersome and interfere with our functioning normally.

For example, if you happened to do poorly on an exam, were criticized by someone important to you, broke up with someone, or had an accident, you may find it difficult to stop worrying and thinking about the troubling event. Researchers find a gender difference in worrying: Compared to men, women report more worrying and more recurring negative thoughts (Robichaud et al., 2003). Although it's good advice to "Just stop worrying about it," such advice is often very difficult to follow. The harder you try to stop worrying about something, the more you may worry about it. Fortunately, clinicians have developed a number of helpful cognitive-behavioral techniques that can be used to solve a variety of psychological or behavior problems. We'll discuss programs to stop recurring and troubling thoughts, to change negative thoughts into positive ones, and to deal with mild insomnia.



How do I battle crazy thoughts?

Thought-Stopping Program

Could you not think about a white bear?

Researchers asked college students to try very hard to suppress or stop any thoughts having to do with a large white bear. But researchers found that no matter how hard students tried to suppress worrisome negative thoughts, they kept coming back (Borton, 2002). These kinds of recurring and unwanted thoughts are called intrusive thoughts.

Intrusive thoughts **are thoughts that we repeatedly experience, are usually unwanted or disruptive, and are very difficult to stop or eliminate.**

Researchers found that just trying to stop thinking about something, called ***thought suppression,*** is not very effective, especially when the thoughts involve emotional situations and especially if you are under a lot of stress (G. J. Beck et al., 2006; Wenzlaff & Luxton, 2003). Instead of using thought suppression (trying not to think that thought), which is not effective, researchers suggest using a mental program that either distracts us or helps us change our goals (Wenzlaff & Wegner, 2000). For example, we'll describe a cognitive-behavioral program to identify and change intrusive thoughts. This program can be carried out on one's own or with the help and support of a therapist.

Here's a real-life example of Carol, who couldn't stop thinking about her former boyfriend, Fred, with whom she had just broken up. No matter how much she tried, she thought about Fred almost every day, and her thinking about breaking up with Fred triggered a chain of other negative thoughts about herself: "I feel that I am a failure. I feel ugly and useless. I keep thinking about not being able to have a relationship. I feel really depressed and I don't want to do anything" (G. L. Martin, 1982).

Carol's problem is that she has been unable to stop the intrusive thoughts about Fred, which result in her feeling depressed. An effective cognitive-behavioral technique for stopping intrusive thoughts has three steps.

How do I stop thinking about my former boyfriend?

1 Self-Monitoring

In all behavior-changing procedures, the first step is ***self-monitoring,*** which is observing one's own behavior without making any changes. In Carol's case, it meant that for one week she wrote down all depressing thoughts about Fred that lasted for more than a couple of minutes. In addition, the therapist asked Carol to bring in pictures of herself that showed her in pleasurable activities. These pictures would provide cues for thinking rational thoughts.

2 Thought Stopping

Each time Carol began to experience a disturbing thought, she would stop what she was doing, clasp her hands together, close her eyes, silently yell "Stop!" to herself, and silently count to ten. This was the ***thought-stopping procedure.***

3 Thought Substitution

After counting silently to ten, she would open her eyes and take five photographs out of her purse. She would look at each photograph and read what she had written on the back. For example, one photograph showed her about to board an airplane for a trip. On the back she had written, "I'm my own boss. My life is ahead of me. I can do what I want to do." Carol would then think about the trip and how much she liked to travel. She would do the same for all five photographs.

This ***thought-substituting procedure*** took 1–2 minutes. After that, she would return to whatever she had been doing.

During Carol's first week of self-monitoring, she thought about Fred constantly and spent from 15 minutes to an hour each day crying. However, after using the thought-stopping and thought-substituting procedures for eight weeks, Carol had reduced the time thinking about Fred to the point that she rarely cried or was depressed. A follow-up interview four months after therapy revealed that Carol was no longer having intrusive thoughts about Fred, was no longer depressed, had developed no new symptoms, and had a new boyfriend (G. L. Martin, 1982).

In Carol's case, thought suppression alone (trying not to think that thought) did not stop intrusive thoughts about Fred. What Carol and most individuals with this problem need is a thought-stopping plus a substitution program, which together are very effective (Borton, 2002).

As you'll see next, thought substitution is a very useful technique for a number of problems, including fear and anxiety.

Thought Substitution

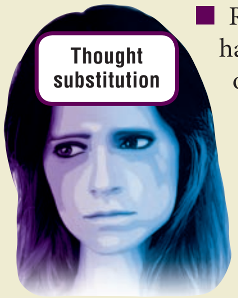
How can I change fearful thoughts?

For many years Rose was trapped in her house by intrusive thoughts that resulted in an intense fear of going out into public places, which is called ***agoraphobia.*** If she even thought about going outside to do her shopping, she felt pain in her arms and chest, she began to perspire, her heart beat rapidly, and her feet felt like rubber. However, after cognitive-behavioral therapy, she overcame her agoraphobia.

As part of the overall therapy program, a cognitive therapist asked Rose a number of questions to identify her irrational thoughts. For example, she may have overgeneralized, thinking, "The last time I went out I was terrified; it's sure to happen again." Or Rose may have engaged in polarized thinking: "All my happiness is right here in this house; nothing outside could give me any pleasure." Her thinking might have been distorted by selective attention, such as remembering all those activities outside the house that terrified her and forgetting all those activities that she had once found pleasurable, such as shopping and going to movies.

Rose was asked to make a list of all her irrational thoughts on one side of a sheet of paper. Then, next to each irrational thought, she was asked to write down a rational response that could be substituted for the irrational one. Here are some examples:

Irrational Thoughts	Rational Thoughts
■ I am much safer if I stay at home.	■ Rarely has anything bad happened when I have gone out.
■ I feel more protected if I do not have to walk through crowds.	■ I have never been harmed by a crowd of people.
■ I think something awful will occur if I go to a supermarket.	■ Thousands of people go to supermarkets and do their shopping unharmed.
■ I can't bear the thought of going to a movie theater.	■ Many people enjoy going to movies.



Thought substitution

Like Rose, you can follow the same three steps of the thought-substitution program, which is a very effective technique for changing feelings and behaviors.

1 Through self-monitoring, write down as many irrational thoughts as possible. If you are in a habit of thinking irrational thoughts, it may require special attention to identify them.

2 Next to the column of irrational thoughts, compose a matching list of rational thoughts. The rational thoughts should be as detailed or specific as possible.

3 Begin to practice substituting rational thoughts for irrational ones. Each time you make a substitution, give yourself a mental reward for your effort.

How do I change my fearful thoughts so I can go out in public?

Photo Credit: © Rob Bartee/SuperStock

One reason therapists give clients homework, such as using thought substitution in daily life, is to encourage clients to practice thinking rationally (A. T. Beck & Weishaar, 2008). Cognitive-behavioral therapists see irrational thoughts and beliefs as the primary causes of emotional and behavioral problems (Dobson, 2009).

Worrisome, annoying, and irrational thoughts are one of the major causes of insomnia, which can also be treated with a cognitive-behavioral program.

Treatment for Insomnia

How can I get to sleep?

Two major causes of insomnia are excessive worry and tension. There are several nondrug treatments for insomnia that differ in method, but all have the same goal: to stop the person from excessive worrying and reduce tension. One proven cognitive-behavioral method to reduce insomnia is to establish an optimal sleep pattern (Bootzin & Rider, 1997; Means & Edinger, 2006).

Establishing an Optimal Sleep Pattern

By following the eight steps below, your sleep pattern will become more regular and efficient and help reduce insomnia.

Cognitive-behavioral program for insomnia

1. Go to bed only when you are ***sleepy,*** not by convention (it's time for bed) or habit.
2. Put the ***light out*** immediately when you get into bed.
3. ***Do not read or watch television*** in bed, since these are activities that you do when awake.
4. If you are not asleep within ***20 minutes,*** get out of bed and sit and relax in another room until you are ***sleepy and tired*** again. Relaxation can include tensing and relaxing one's muscles or using ***visual imagery,*** which involves closing one's eyes and concentrating on some calm scene or image for several minutes.
5. ***Repeat step 4*** as often as required and also if you wake up for any long periods of time.
6. ***Set the alarm to the same time each morning*** so that your time of waking is always the same. This step is very important because oversleeping or sleeping in is one of the primary causes of insomnia the next night.
7. ***Do not nap during the day*** because it will throw off your sleep schedule that night.
8. ***Follow this program*** rigidly for several weeks to establish an efficient and regular pattern of sleep.

Results. Nondrug treatment programs, such as the eight-step program described here, were among the most effective programs for significantly decreasing insomnia (Means & Edinger, 2006).

We have discussed several cognitive-behavioral techniques that can be used on one's own or with the aid of a therapist. These techniques are effective for treating a wide range of mild to severe mental problems (Dobson, 2009).

Summary Test

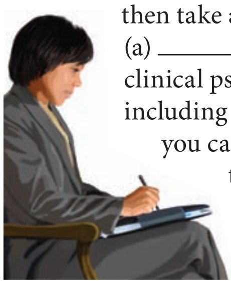
A. Historical Background

1. In the early 1800s, the popular belief that mental patients could be helped to function better by providing humane treatment in a relaxed and decent environment was called (a) __________. In the early 1950s, the first drugs to reduce schizophrenic symptoms were discovered. These drugs, called (b) __________, reduced the effects of the neurotransmitter (c) __________.

2. Following the use of phenothiazines, many mental patients were released from mental hospitals and returned to the community to develop more independent and fulfilling lives; this process was called (a) __________. People with mental disorders that do not require hospitalization often seek treatment in (b) __________ centers.

B. Questions about Psychotherapy

3. If you go to medical school, receive an MD degree, and then take a psychiatric residency, you can become a (a) __________. If you go to graduate school in clinical psychology and complete a PhD program, including at least one year of work in a clinical setting, you can become a (b) __________. If you go to graduate school in psychology or education and complete a PhD program, including work in a counseling setting, you can become a (c) __________.



4. Therapy in which the therapist and client talk about the client's symptoms and problems with the goal of reaching or identifying the cause of the problem is called (a) __________ therapy. Therapy that involves the application of learning principles and focuses on identifying and changing specific behaviors is called (b) __________ therapy. Therapy that involves the use of various psychoactive drugs, such as tranquilizers and neuroleptics, to treat mental disorders is called (c) __________ therapy.

C. Insight Therapies

5. Freud developed one of the first forms of insight therapy, which he called (a) __________. At the core of psychoanalysis is the idea that psychological and physical symptoms arise from (b) __________ that a person cannot voluntarily uncover or recall.

6. Freud developed two techniques that he believed provide clues to unconscious thoughts and conflicts: When clients are encouraged to talk about any thoughts or images that enter their heads, this is called (a) __________; when a therapist looks for hidden meanings and symbols in dreams, this is called (b) __________.

7. During the course of therapy, a patient will project conflict-ridden emotions onto the therapist; this process is called (a) __________. Working through transference is one of the two essential requirements for improvement in psychoanalysis; the other is that the patient achieves (b) __________ into the causes of his or her problem. A patient's reluctance to work through feelings or recognize unconscious conflicts and repressed thoughts is called (c) __________.

8. Increasing pressure to use briefer versions of psychotherapy resulted in a shortened form of traditional psychoanalysis. This new version uses some of the same principles, such as dealing with transference, but has the therapist taking a more active role and dealing with a more specific problem; this approach is called __________ psychotherapy.

9. A form of insight therapy developed by Carl Rogers emphasizes our creative and constructive tendencies and the importance of building caring relationships. This is called (a) __________ therapy. One of its basic techniques is to restate or (b) __________ the client's concerns and feelings.

10. Rogers believed that the therapist's characteristics foster growth and change. The therapist needs to have the ability to understand what the client is saying and feeling, a trait called (a) __________; the ability to communicate caring, respect, and regard for the client, called (b) __________; and the ability to be real and nondefensive in interactions with the client, called (c) __________.

11. Another form of insight therapy is the cognitive therapy developed by Aaron Beck. The basic assumption of Beck's cognitive theory is that our (a) __________ negative thoughts distort how we perceive and interpret things, thus influencing our behaviors and feelings. For example, making blanket judgments about yourself on the basis of a single incident is called (b) __________. Sorting information into one of two categories is (c) __________. Focusing on one detail so much that you do not notice other events is using (d) __________. Beck believes that maladaptive thought patterns cause a distorted view of one's world, which in turn may lead to various emotional problems.

12. Cognitive therapy has been shown to have approximately the same effectiveness as do drugs in treating major __________ and has been used effectively to treat other psychological problems.

D. Behavior Therapy

13. Therapy that emphasizes treatment of specific behaviors and working toward specific goals without focusing on mental events or underlying unconscious factors is known as __________ therapy. This form of therapy is based on classical and operant conditioning principles.

Photo Credit: (#1) National Library of Medicine, #A-13392

14. A technique of behavior therapy in which the client is gradually exposed to the feared object while simultaneously practicing relaxation is called (a) ________________. As part of this technique, the client must prepare a list of feared stimuli, arranged in order from least to most feared; this is called a (b) ________________ hierarchy. Another technique is for the client to be gradually exposed to the actual feared or anxiety-producing situation; this is called (c) ________________ exposure.

15. One form of therapy combines two methods: changing negative thoughts by substituting positive ones, and changing unwanted or disruptive behaviors by learning and practicing new skills to improve functioning. This approach is called ________________ therapy.

E. Review: Evaluation of Approaches

16. Sigmund Freud developed psychoanalysis, whose basic assumption is that emotional problems are caused by underlying (a) ________________. Techniques used to uncover unconscious conflicts include (b) ________________ and ________________.

17. Carl Rogers developed (a) ________________ therapy, whose basic assumption is that the client is responsible for change and has the capacity to grow and reach his or her full potential. Techniques include (b) ________________ the client's concerns; therapists must also show the characteristics of empathy, positive regard, and genuineness.

18. Aaron Beck's cognitive theory assumes that automatic, negative, and irrational (a) ________________ can color our feelings and actions, distort our perceptions, and result in various problems. Its techniques include recognizing negative thoughts and (b) ________________ positive ones.

19. An approach to therapy based on learning principles is called (a) ________________ therapy, whose basic assumption is that emotional problems are (b) ________________ and thus can be unlearned by using learning principles. Its techniques include systematic desensitization, role-playing, imitation, and modeling.

20. Despite differences in approaches and techniques, the five most popular forms of psychotherapy differ little in (a) ________________, except for a small number of disorders, such as phobias, panic attacks, and depression, in which (b) ________________ therapy is found to be more effective. Most improvement in therapy occurs in a relatively short period of (c) ________________.

21. One reason therapies tend to be equally effective is that they all share ________________. For example, the development of a supportive and trusting relationship between therapist and client results in an accepting atmosphere in which the client feels willing to admit problems and is motivated to work on changing.

F. Cultural Diversity: Different Healer

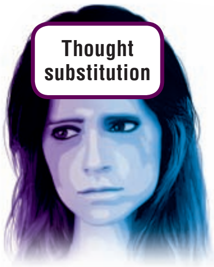
22. In many cases, the healers in Asia and Africa are as effective as Western therapists. One explanation is that these healers may rely on the (a) ________________ effect, which is found to produce significant improvement in 10–30% of Western patients. Another is that the healers' ceremonies may involve some of the (b) ________________ that underlie the effectiveness of Western therapy.

G. Research Focus: EMDR—New Therapy

23. Researchers have shown that three different therapies are effective ways to reduce the distress, anxiety, and traumatic memories in individuals suffering from (a) ________________, or PTSD. These three therapies are (b) ________________, or EMDR, (c) ________________, and ________________. Researchers believe that EMDR may work because it is similar to another therapy called (d) ________________.

H. Application: Cognitive-Behavioral Techniques

24. Behavior or cognitive-behavioral therapy usually involves three steps in changing thought patterns. The first step is observing one's own behavior without making any changes; this is called (a) ________________. The second step is to identify those (b) ________________ thoughts that need to be changed. The third step is to (c) ________________ a positive thought for a negative one. Another step that is sometimes included is to actively stop (d) ________________ thoughts.



__Answers:__ 1. (a) moral therapy, (b) phenothiazines, (c) dopamine; 2. (a) deinstitutionalization, (b) community mental health; 3. (a) psychiatrist, (b) clinical psychologist, (c) counseling psychologist; 4. (a) insight, (b) behavior, (c) medical; 5. (a) psychoanalysis, (b) unconscious conflicts; 6. (a) free association, (b) dream interpretation; 7. (a) transference, (b) insight, (c) resistance; 8. short-term dynamic; 9. (a) client-centered, (b) reflect; 10. (a) empathy, (b) positive regard, (c) genuineness; 11. (a) automatic, (b) overgeneralization, (c) polarized thinking, (d) selective attention; 12. depression; 13. behavior; 14. (a) systematic desensitization, (b) stimulus, (c) in vivo; 15. cognitive-behavioral; 16. (a) unconscious conflicts, (b) free association, dream interpretation; 17. (a) client-centered, (b) reflecting or restating; 18. (a) thoughts, (b) substituting; 19. (a) behavior, (b) learned; 20. (a) effectiveness, (b) behavior or cognitive-behavioral, (c) time; 21. common factors; 22. (a) placebo, (b) common factors; 23. (a) posttraumatic stress disorder, (b) Eye Movement Desensitization and Reprocessing, (c) exposure therapy, cognitive-behavioral therapy, (d) exposure; 24. (a) self-monitoring, (b) negative or automatic, (c) substitute, (d) intrusive or annoying

Can Virtual Reality Be More than Fun & Games?

Most people experience a traumatic event at some point in their life, but for some, the trauma has lasting effects that interfere with their daily functioning. People who are plagued by nightmares, flashbacks, and constant stress as a result of a traumatic experience, such as abuse, rape, burglary, or watching a person die, are often in desperate need of treatment. For many years, therapists have been working with such clients by helping them confront their fears in a systematic, step-by-step approach.

As you may expect, many clients who have intense fears are reluctant to undergo therapy requiring them to confront the very fear they so badly want to avoid. A relatively new treatment option for these clients is virtual-reality therapy, where they can vividly experience the feared object or situation in a safe and controlled manner. That's right, virtual reality is no longer only about experiencing fun adventures or fantasies. It's a powerful treatment technique. For instance, virtual-reality therapy can help a socially anxious client speak to intimidating crowds of people, or help a client with a phobia of spiders to approach and hold a hideous-looking spider, or even help a client with an intense fear of heights stand on a 30-story building and look straight down.

One of the major advantages of virtual-reality therapy is it can be used when a client's fear is not something a therapist can easily expose him or her to. For this reason, virtual-reality therapy is being used to treat Iraq war veterans diagnosed with PTSD as a result of traumatic combat experiences. These veterans describe the scene that haunts them, and the therapist uses a computer program to create a virtual environment that consists of the key elements of the reported traumatic experience. The handheld joystick is used to navigate through the three-dimensional scene, and special goggles help make the scene more real, so real in fact that users feel as though they are back in Iraq. The reenactment takes place on a vibrating platform so the veteran can feel the humming of the tank's motor or the rumbling of explosives being set off. Sounds and smells (such as voices, gunshots, and odors) can be incorporated to add to the realness of the situation. This process is gradual, beginning with only a few elements of the traumatic experience and adding more elements until the scenes become gruesomely realistic, with images of people getting blown up and terrifying sounds of screaming. The goal is that eventually the veteran can go through an intense re-creation without being overcome with fear.

Because research data on the effectiveness of virtual-reality therapy have been so positive, qualified mental health professionals can now lease software so they can administer treatments in their own offices. The current technology is not nearly as sophisticated as the world portrayed in *The Matrix* films, but nevertheless, based on clients' intense reactions, the virtual scenes are realistic enough. (Adapted from P. L. Anderson et al., 2005; APA, 2008b; H. G. Hoffman, 2004; Jardin, 2005; Osborne, 2002; A. Rizzo et al., 2009; S. Rizzo, 2008; Z. Rosenthal, 2007; Rothbaum, 2009; Saladin et al., 2006; J. Williams, 2009)

QUESTIONS

1 Can virtual-reality therapy be used to treat drug addiction, even though it isn't a fear resulting from a traumatic experience? Explain.

2 What type of DSM-IV-TR disorder is fear of spiders and fear of heights?

3 What are some other advantages of virtual-reality therapy over traditional therapy methods?

4 What are some of the physical symptoms you would expect these veterans to exhibit during the reenactment that seems so real?

5 Which type of therapeutic approach and technique is virtual-reality therapy most like?

6 What type of mental health professional(s) would most likely administer virtual-reality therapy?

Suggested Answers to Critical Thinking

1. Yes, virtual-reality therapy can be used to treat drug addiction. A therapist guides a patient through a virtual world filled with temptations, which brings the patient's cravings in the outside world into therapy. When temptations arise, the patient's cravings intensify, and since patients don't take drugs in the virtual world, they learn to cope with cravings without using drugs.
2. A fear of spiders and fear of heights are considered to be specific phobias, which are characterized by marked and persistent fears that are unreasonable and triggered by anticipation of, or exposure to, a specific object or situations (in this example, spiders and heights).
3. Additional advantages of virtual-reality therapy include that it can be less expensive and safer than other treatment methods, such as traditional exposure. The therapist can control the intensity of the experience and stop immediately if the patient panics. It also provides complete confidentiality and reduces possible embarrassment because exposure doesn't have to take place in public settings.
4. A wide range of physical symptoms may occur. They include pounding heart, high blood pressure, shortness of breath, muscle tension, heightened sweat gland activity, dilated pupils, and dry mouth.
5. Virtual-reality therapy is essentially an application of a type of behavior therapy called systematic desensitization, which is a method of gradually exposing patients to a feared object or situation in real life or through the use of imagination.
6. Mental health professionals who could provide virtual-reality therapy are those who provide psychotherapy for psychological disorders, which would primarily include clinical and counseling psychologists as well as a smaller proportion of psychiatrists.

Stereotypes

Why did he take a $90,000 pay cut?

Lawrence Graham wanted to get a job at a country club and had phoned numerous clubs to set up personal interviews. Here's what happened when he arrived for one of his interviews.

"We don't have any job openings—and if you don't leave the building, I will have to call security," the receptionist said at the first club Graham visited.

"But I just spoke to Donna, your dining manager, and she said to come by and discuss the waiter job."

"Sorry, but there are no jobs and no one here named Donna" (Graham, 1995, p. 4).

A posh country club would offer Graham only the job of a busboy.

Graham finally got two job offers and decided on the exclusive Greenwich Country Club. This club had been in existence for 100 years and was *the* country club in the very affluent, prestigious, and White town of Greenwich, Connecticut. The club's members included a former president, a number of high-ranking government officials, and dozens of *Fortune* 500 executives, bankers, and Wall Street lawyers.

Although Graham wanted a job as a waiter, he was hired to be a busboy. Except when one of the members wanted something and deliberately looked for him, Graham's job as a busboy made him quite invisible and able to overhear members' conversations.

"Here, busboy. Here, busboy," a woman called out. "Busboy, my coffee is cold. Give me a refill."

"Certainly, I would be happy to," said Graham.

Before he returned to the kitchen, Graham heard the woman say to her companion, "My goodness. Did you hear that? That busboy has diction like an educated White person" (Graham, 1995, p. 12).

In real life, Lawrence Graham was a Harvard Law School graduate, had a job as an associate in a New York law firm, and earned $105,000 a year. Although he was ready to move up the social ladder, Graham, who is African American, received no invitations to join a country club, as his White associates did. So to find out what goes on in country clubs that do not admit African Americans, he got in the only way he could, as a busboy making $7 an hour.

Graham's example points out how people often make judgments about others on the basis of physical appearance and accompanying stereotypes, which are both major topics of social psychology.

Social psychology is a broad field whose goals are to understand and explain how our thoughts, feelings, perceptions, and behaviors are influenced by the presence of, or interactions with, others.

One relatively new, rapidly growing, and important subarea of social psychology is cognitive social psychology.

Cognitive social psychology is a subarea of social psychology that focuses on how cognitive processes, such as perceiving, retrieving, and interpreting information about social interactions and events, affect emotions and behaviors and how emotions and behaviors affect cognitions (Roese, 2001).

Social psychologists study how we form impressions and perceive others, how we form attitudes and stereotypes, how we evaluate social interactions, and why racism exists—all of which are involved in Lawrence Graham's story.

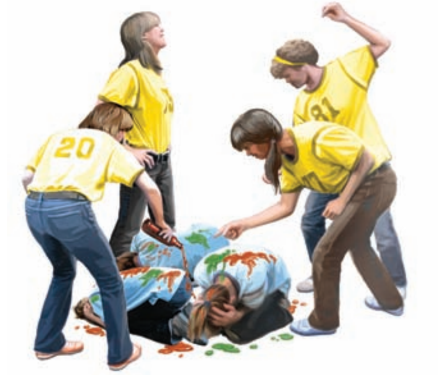
Another major topic of social psychology is how people behave in groups.

Behavior in Groups

Why did the girls turn violent?

The touch football game had been going on for years and was considered a rite of passage for incoming seniors. During the game, some minor hazing usually took place, such as senior girls dumping various kinds of food (ketchup, whipped cream, syrup) on junior girls. For this game, the time and place were kept secret from school administrators. Also, several parents arranged to have kegs at their homes so that the underage girls could drink beer before going to the game.

About 10 minutes into the junior-senior touch football game, something happened and the game turned ugly and violent. The senior girls started to act in violent ways that just happened to be videotaped by another student. Later, as CNN played the tape over and over, everyone wondered how these particular senior girls, who came from a well-to-do Chicago suburb and went to a good high school, could have done such disgusting things.



Senior girls engage in violent hazing of juniors while about 100 watch.

According to the video (above illustration) and police reports, junior girls were beaten, slapped, kicked, splattered in the eyes with Tabasco sauce and vinegar, hit with buckets, covered with animal intestines and urine, and smeared with blood, fish guts, mud, and feces. Five girls ended up in the hospital, some requiring stitches. During the violent hazing, about a hundred students just stood and watched, not trying to stop the brawl (L. Black & Flynn, 2003). What kind of group pressure causes normal people to submit to being hazed, and what kind of group pressure turns normal people into violent and ugly hazers?

What's Coming

We'll discuss how we perceive people, how we explain the causes of our behaviors, why we develop attitudes, and how we respond to persuasion. We'll also explore a variety of social influences and group behaviors, such as what makes hazing so popular, how we respond to group pressures, what motivates us to help others, and why we behave aggressively.

We'll begin with Graham's story, which raises the question of how we form impressions of others.

A. Perceiving Others

Person Perception

How do you form first impressions?

Compare the photo of Lawrence Graham on the left with that on the right. In the left photo, your first impression is that Graham is a busboy or waiter, while in the right photo, your first impression is that Graham is a confident businessman or professional. Your first impressions, which were formed in seconds, with little conscious thought, and were biased by your past experiences, are part of person perception.

At country clubs, Graham was offered jobs as a busperson.

Person perception refers to seeing someone and then forming impressions and making judgments about that person's likability and the kind of person he or she is, such as guessing his or her intentions, traits, and behaviors.

As you formed a first impression of Graham from each photo, four factors influenced your judgment (L. S. Newman, 2001).

1 Physical appearance. Your initial impressions and judgments of a person are influenced and biased by a person's physical appearance. For example, Graham makes a very different first impression when he looks like a busboy or a professional.

2 Need to explain. You don't just look at a person, but rather you try to explain why he looks, dresses, or behaves in a certain way. You might explain that Graham-as-busboy is working his way through college, while Graham-as-professional is successfully developing his career.

3 Influence on behavior. Your first impressions will influence how you would like or interact with a person. For example, if your first impression of Graham is as a $7-an-hour busboy, you would interact very differently than if your impression of him was as a $105,000-a-year professional working for a large corporation.

Graham was actually a graduate of Harvard Law School.

4 Effects of race. Researchers found that members of one race generally recognize faces of their own race more accurately than faces of other races (Ferguson et al., 2001). This means we may perceive faces that are racially different from our own in a biased way because they do not appear as distinct as faces from our own race. Further evidence of racial bias occurring in first impressions is found in research showing that the area of the brain associated with emotional vigilance becomes more activated when White people view photos of unfamiliar Black, as compared to unfamiliar White, faces (Fiske, 2006).

Researchers report that first impressions, such as the one you make of Graham, usually occur automatically and function to influence or bias future social interactions in a positive or negative direction (Andersen et al., 2007; L. S. Newman, 2001). One factor that plays a major role in person perception, especially forming first impressions, is physical attractiveness.

Physical Appearance

What makes a face attractive?

Researchers found that, for better or worse, a person's looks matter, since people who are judged more physically attractive generally make more favorable impressions (D. K. Marcus & Miller, 2003). To determine why a face is judged attractive, researchers created faces by combining and averaging physical features taken from different faces. Researchers could make faces more or less attractive by averaging more (32) or fewer (16) faces (Langlois et al., 1994). For example, the face in the left photo, which was rated very attractive, was actually created by averaging thousands of faces (Johnston, 2000). It turns out that average faces are more attractive than the originals, and the preference for average faces begins in infancy, as babies stare at composite faces longer (Langlois, 2009).When faces of attractive women were shown to heterosexual men, the men's brain scans showed that looking at attractive faces activated the brain's reward/pleasure center (p. 330), the same center that is activated by food, sex, and drugs (cocaine) (Aharon et al., 2001).

How attractive is this woman?

Evolution. Some researchers believe that physical attraction is completely instinctual and not based on logic. Research suggests that some physical characteristics are considered more universally attractive (Jayson, 2009a). For example, researchers found that both within and across cultures, there is strong agreement (correlation about 0.90) among Whites, African Americans, Asians, and Hispanics about which faces of adults and children are and are not attractive (Langlois et al., 2000). According to evolutionary psychologists, judging and valuing attractiveness may have evolved and become a "built-in" ability because attractiveness was a visible sign of a person having good genes, being healthy, and becoming a good mate (Lie, 2009; Quill, 2009).

According to evolutionary psychologists, men are most attracted to youthful women who have an "hourglass figure" (hips larger than waist), which signals a childbirth advantage. Women are most attracted to men who have masculine faces, with a larger jaw and greater muscle mass, which suggests higher testosterone levels (Jayson, 2009a). Interestingly, when women are ovulating, which is the most fertile time in their monthly cycle, their preference for more masculine faces and masculine bodies intensifies (Gangestad, 2009).

Women prefer men with more masculine faces.

Men prefer women with "hourglass figures."

Stereotypes

What could bias medical treatment?

On the right are photos of actors who played the roles of patients complaining of chest pains. While describing their symptoms, the actor-patients were videotaped. These videotapes were shown to over 700 physicians who were asked to recommend treatments. Because the actor-patients all described the same physical symptoms, all the physicians should have generally recommended the same treatments. However, physicians recommended different treatments that depended on the physicians' particular sexual and racial stereotypes (Schulman et al., 1999).

Which of these individuals received the best treatment for heart problems?

Stereotypes **are widely held beliefs that people have certain traits because they belong to a particular group. Stereotypes are often inaccurate and frequently portray the members of less powerful, less controlling groups more negatively than members of more powerful or more controlling groups.**

Stereotypes played an important role in the study we just described. Although the actor-patients reported the same symptoms and should have received about the same kinds of treatment, physicians were 40% less likely to recommend sophisticated medical tests for women and African Americans compared to White men (Schulman et al., 1999). More recent research also found that African Americans were less likely than Whites to receive expensive medical procedures (*USA Today,* 2005).

These studies show that racial and sexual stereotypes, which may occur automatically and without awareness, may bias the physicians' perceptions and judgments (Andersen et al., 2007). As you'll see next, once negative stereotypes are formed, they are difficult to change.

Development of Stereotypes

Psychologists believe that we develop stereotypes when parents, peers, teachers, and others reward us with social approval for holding certain attitudes and beliefs. There are also cultural pressures to adopt certain values and beliefs about members of different groups. For example, in the weight-conscious culture of the United States, there is an emphasis on being thin (see Module 15), so we might expect a negative stereotype to apply to people who are overweight. In fact, research shows that people have a significant bias against hiring overweight job applicants, especially overweight women (Pingitore et al., 1994). Other research shows that after taking into account factors such as age, race, and sex, people who are perceived as more attractive make more money (Judge et al., 2009). Another study found that in a trivia competition, a situation in which working with a partner with a high IQ provides a distinct advantage, people are willing to sacrifice 12 IQ points in a partner to have one who is thin (Caruso, 2009). These biases are examples of negative stereotypes, which are often accompanied by prejudice and discrimination.

Why do you think I wasn't hired?

Prejudice **refers to an unfair, biased, or intolerant attitude toward another group of people.**

An example of prejudice is believing that overweight women are not as intelligent, competent, or capable as women of normal weight.

Discrimination **refers to specific unfair behaviors exhibited toward members of a group.**

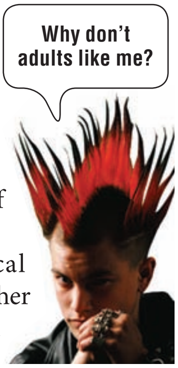
An employer's bias against hiring overweight applicants is an example of discrimination.

The history of the United States provides many examples of racist and sexist cultural stereotypes, such as beliefs that women are not smart enough to vote and that African Americans are inferior to Whites (Swim et al., 1995). Research shows that some stereotypes, including racial prejudice, are so much a part of our society that they begin developing as early as 6 years of age (A. S. Baron & Banaji, 2006).

One reason we frequently use stereotypes to make judgments about people is that stereotypes save us thinking time.

Functions of Stereotypes

Social cognitive psychologists suggest that, just as we have developed physical tools, such as hammers and saws, to help us build things more efficiently, we have also developed cognitive tools, such as stereotypes, to help us think and make decisions more efficiently. For example, instead of having to analyze in detail the person in the photo below, you immediately notice the person's unique characteristics, assign the person to a social group, such as teenage-punker, and use the information stored in your "teenage-punker" stereotype: disregards standard social customs and fashions, is independent, dislikes authority, goes to rave parties, experiments with drugs, and so on. This example shows that stereotypes are frequently used because they serve at least two major functions (Banaji, 2005; D. J. Schneider, 2004).



Why don't adults like me?

Thought-saving device. Stereotypes help us conserve time and energy when making decisions in social situations. By using stereotypes, we make quick (and sometimes inaccurate) decisions and thus save time and energy by not having to analyze an overwhelming amount of personal and social information.

Alertness and survival. Recent neurological research found that the sight of a stranger of another race leads to heightened physiological arousal, which likely reflects unconscious biases and a natural awareness of individuals of unfamiliar groups (such as race) (A. Olsson et al., 2005). Thus, one function of stereotypes is to make us alert and cautious around members of an unfamiliar group.

However, a major problem with stereotypes is they are very difficult to change because they occur automatically and without our awareness of having used them to make judgments (D. J. Schneider, 2004). Another reason stereotypes are difficult to change is that we often dismiss information that contradicts or doesn't fit our stereotypes (Banaji, 2006). This means biased stereotypes can live on and lead to inaccurate judgments and decisions in social situations.

Another view of stereotypes is they are like having information categories in the brain, which are called schemas, our next topic.

A. Perceiving Others

Schemas

How are schemas like social filters?

When Dr. Harriet Hall received her medical degree in 1970, few women were in medicine and even fewer women joined the military. Dr. Hall was the only female doctor at David Grant USAF Medical Center and the only female military doctor in Spain. Throughout her career, she had to fight for acceptance from just about everyone. Even a 3-year-old daughter of a patient said, "Oh, Daddy! That's not a doctor, that's a lady." After spending several years as a medical officer in Spain, she returned to the United States, learned to fly, and became a flight surgeon. Dr. Hall earned a pilot's license despite being told "women aren't supposed to fly," a phrase she chose as the title of her memoirs.

Why was Dr. Hall shown less respect than her male peers?

With such exceptional accomplishments, Dr. Hall had to tolerate prejudice and discrimination simply because she chose to work in a male-dominated field. For instance, when she applied for specialty training as a radiologist, she was rejected because the program gave preference to males, as females were not considered to have stable, long-term careers. While married to a civilian, she was not allowed to live in base housing or receive the dependent allowances that her male colleagues got because wives were classified as dependents and husbands were not (H. A. Hall, 2008). One reason people responded to Dr. Hall in sexist ways is they had developed mental categories, called schemas.

Schemas **are mental categories that, like computer files, contain knowledge about people, events, and concepts. Because schemas affect what we attend to and how we interpret things, schemas can influence, bias, and distort our thoughts, perceptions, and social behaviors.**

Sexist schemas of women working in medical fields and in the military put women like Dr. Hall at a disadvantage compared to their male colleagues. Even today, successful women in male-dominated fields are often regarded more negatively than their male colleagues (M. E. Heilman & Okimoto, 2007). For instance, researchers asked participants to read memos announcing the hiring of a new executive. One group read a description about a male executive, and another group read the same description about a female executive. People viewed the male leader as professional, capable, and likable, and the female leader as mean, ruthless, and stubborn. Thus, schemas influence our thoughts, behaviors, and feelings toward others (J. E. Young et al., 2006).

Kinds of Schemas

Person schema has information on how to act with a new date.

Schemas are part of **social cognition,** which studies how and what people learn about social relationships. Schemas, which are like hundreds of different information files in your brain, are generally divided into four types: person, role, event, and self schemas.

Person schemas **include our judgments about the traits that we and others possess.**

For example, when meeting someone new, we may rely on person schemas to provide general information about that person. Person schemas that contain general information about people who have membership in groups are **stereotypes** (Wyer, 2007).

Role schemas **are based on the jobs people perform or the social positions they hold.**

The reason you often ask "What do you do?" is so you can use your role schemas to provide missing information about the person and provide mental shortcuts about what you might say or how you might act in social situations.

Event schemas, **also called scripts, contain behaviors that we associate with familiar activities, events, or procedures.**

The event schema for graduation is to celebrate getting your degree. In contrast, the event schema for a college class is to be silent, pay attention, and take notes. Event schemas help us know what to expect and provide guidelines on how to behave in different kinds of situations.

Self schemas **contain personal information about ourselves, and this information influences, modifies, and distorts what we perceive and remember and how we behave.**

What's interesting about our self schemas is that they overemphasize our good points, which explains why being criticized in public easily hurts our feelings.

We especially look for information or feedback to support our schemas and tend to disregard information that doesn't (Wyer, 2007). For this reason, once schemas are formed, they are difficult to change (J. E. Young et al., 2006).

Advantages and Disadvantages

There are two **disadvantages** of schemas. First, schemas may **restrict, bias,** or **distort** what we attend to and remember and thus cause us to overlook important information (Devine et al., 1994). For example, if your self schema is being a good student, you may not pay attention to suggestions from parents or teachers that may make you a better student.

Your person schema may cause you to reject valid criticisms of your work.

The second disadvantage is that schemas are **resistant to change** because we generally select and attend to information that supports our schemas and deny information that is inconsistent with them (Macrae & Bodenhausen, 2000). For example, you might pay attention to positive comments on a class paper and reject any constructive suggestions about ways to improve your writing skills.

Schemas also have **advantages.** For example, if someone says "I'm a freshman," you use your "freshman schema," which contains **information** about how freshmen think and behave, to help you analyze and respond appropriately in this particular social situation. Schemas also provide **guidelines** for how to behave in various social events (event schemas) and help us explain the social behavior of others (role schemas) (J. A. Howard & Renfrow, 2006). Explaining social behavior is one of the most intriguing areas of social cognition, and it's our next topic.

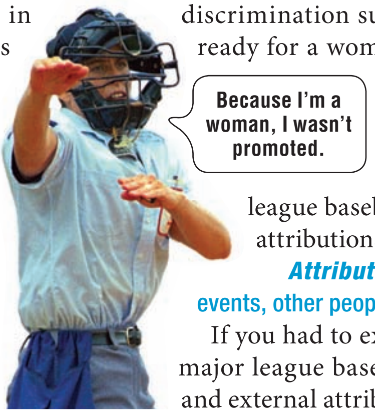
Definition

What is unusual about this umpire?

After 13 seasons and 2,000 games in the minor leagues, this umpire was passed over for promotion to the major leagues and released. An evaluation report by the Office for Umpire Development claimed that this umpire's work had "deteriorated in areas of enthusiasm and execution," even though earlier in the season the rating had been "better than average." What is unusual about this umpire is that she is a woman. Pam Postema (right photo) claims the reason she was passed over for promotion and released was that she was a woman and there are no female umpires in major league baseball. She filed a sex discrimination suit because, as Pam says, "Baseball wasn't ready for a woman umpire no matter how good she was" (S. Reed & Stambler, 1992).



Because I'm a woman, I wasn't promoted.

Most sports fans would have an explanation as to why Pam Postema was not promoted to be an umpire in major league baseball. These kinds of explanations are called attributions.

Attributions are things we point to as the causes of events, other people's behaviors, and our own behaviors.

If you had to explain why there are no female umpires in major league baseball, you would choose between internal and external attributions.

Internal Versus External

A famous social psychologist, Fritz Heider (1958), believed that we all function to some extent like social psychologists as we try to explain everyday behaviors. Heider was the first to distinguish between internal and external causes or attributions for behaviors.

Internal attributions are explanations of behavior based on the internal characteristics or dispositions of the person performing the behavior. They are sometimes referred to as ***dispositional attributions.***

For example, if you used internal attributions to explain why Postema was not made a major league umpire, you would point to her personal characteristics or dispositions, such as saying that she was not a good judge of balls and strikes.

External attributions are explanations of behavior based on the external circumstances or situations. They are sometimes called ***situational attributions.***

If you used external attributions to explain why Postema was not promoted, you would point to external circumstances, such as saying that major league baseball is run by men, and they do not want to have a woman umpire.

Thus, making internal or external attributions has important implications for personal and social behaviors (Derlega et al., 2005). For example, if you use internal attributions, you would say that Postema does not have the skill or talent to be a major league umpire. If you use external attributions, you would say that, although she has the skills, the league discriminated against her because she is a woman. How people make the distinction between internal and external attributions is a rather complicated process.

Kelley's Model of Covariation

How do we decide whether Pam was passed over for promotion because of dispositional or situational factors? To answer this question, social psychologist Harold Kelley (1967) developed the covariation model.

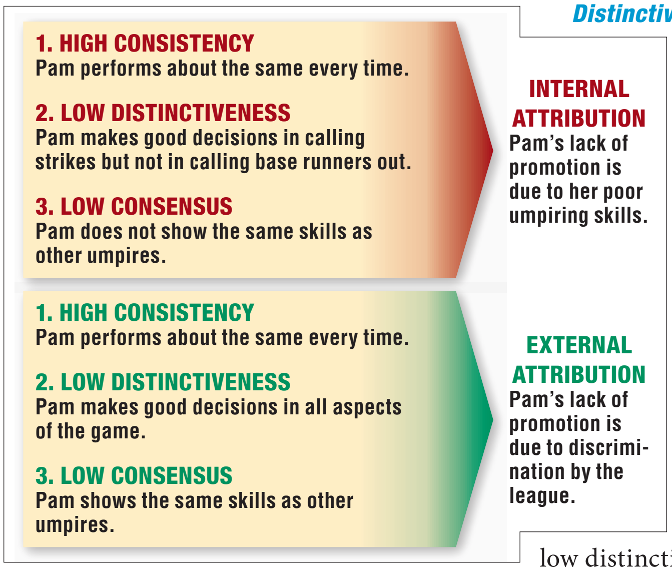
The ***covariation model,*** developed by Harold Kelley, says that, in making attributions, we should look for factors that are present when the behavior occurs and factors that are absent when the behavior does not occur.

Kelley proposed that, in explaining someone's behavior, we should look for information about three factors: consensus, consistency, and distinctiveness (Forster & Liberman, 2007).

Consensus means determining whether other people engage in the same behavior in the same situation.

Consistency means determining whether the person engages in this behavior every time he or she is in a particular situation.

Distinctiveness means determining how differently the person behaves in one situation when compared to other situations.



1. HIGH CONSISTENCY
Pam performs about the same every time.

2. LOW DISTINCTIVENESS
Pam makes good decisions in calling strikes but not in calling base runners out.

3. LOW CONSENSUS
Pam does not show the same skills as other umpires.

INTERNAL ATTRIBUTION
Pam's lack of promotion is due to her poor umpiring skills.

1. HIGH CONSISTENCY
Pam performs about the same every time.

2. LOW DISTINCTIVENESS
Pam makes good decisions in all aspects of the game.

3. LOW CONSENSUS
Pam shows the same skills as other umpires.

EXTERNAL ATTRIBUTION
Pam's lack of promotion is due to discrimination by the league.

How do you decide if internal or external attributions apply to Pam?

In the examples on the left, we have applied the three factors in Kelley's covariation model to Pam Postema's situation. Notice that high consistency, low distinctiveness, and low consensus result in an internal, or dispositional, attribution (fired because she's a poor umpire). But high consistency, high distinctiveness, and high consensus result in an external or situational attribution (fired because of sexual discrimination). Thus, Kelley's covariation model helps us determine if Postema's firing was due to internal or external attributions (Ployhart et al., 2005). However, if we don't follow Kelley's model, we make errors in attributing causes. We'll discuss three errors in making attributions—that is, in deciding what caused what.

B. Attributions

Biases and Errors

Can we make the wrong attributions?

Most people have heard the term *glass ceiling,* which refers to a real but invisible barrier that keeps women and people of color from reaching the top positions in a business or organization. Evidence that there is a thick glass ceiling is clear because only 15 (3%) of *Fortune* magazine's top 500 chairpersons are women and 95% of the senior managers are White men (Y. Cole, 2009; *Fortune,* 2009). One woman who was successful in breaking the glass ceiling is Indra Nooyi (right photo), who became one of the first women of color to head a large organization. Through perseverance, hard work, and a winning personality, she broke through the glass ceiling by becoming chief executive officer at PepsiCo, one of the world's leading food and beverage companies (Useem, 2008). Indra Nooyi is number 3 on the *Forbes* list of the 100 most powerful women and is the highest-ranked female CEO (D. Jones, 2009).

I broke through the glass ceiling.

Breaking through the glass ceiling involves decisions about attributions. Do women and people of color fail to be appointed to senior-level positions because they lack skills and intelligence, which is an internal or dispositional attribution, or because they face discrimination from senior-level White males, which is an external or situational attribution? Although Kelley's covariation model would help decide this issue, many want a quicker way and use the cognitive miser model (S. E. Taylor, 1981).

The *cognitive miser model* says that, in making attributions, people feel they must conserve time and effort by taking cognitive shortcuts.

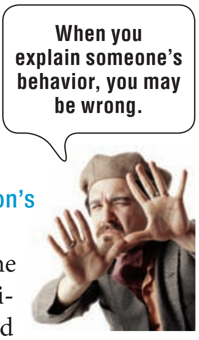
We have discussed cognitive shortcuts that we use in selecting, gathering, remembering, and using information—for example, relying on stereotypes and schemas. Researchers have identified other cognitive shortcuts that we use in making attributions (Forgas et al., 2003; B. Weiner & Graham, 1999). Although these cognitive shortcuts are efficient, they may result in incorrect attributions.

We'll discuss three of the most common biases in making attributions: the fundamental attribution error, the actor-observer effect, and the self-serving bias.

Fundamental Attribution Error

If you believe that women and people of color cannot break through the glass ceiling because they lack the skills and intelligence to do so, you may be making the fundamental attribution error (Langdridge & Butt, 2004).

The *fundamental attribution error* refers to our tendency, when we look for causes of a person's behavior, to focus on the person's disposition or personality traits and overlook how the situation influenced the person's behavior.



When you explain someone's behavior, you may be wrong.

An example of the **fundamental attribution error** would be to conclude that women and people of color cannot break through the glass ceiling because of personal or dispositional factors, such as a lack of assertiveness or intelligence. However, the real reason may be not personal or dispositional factors but the situation: 95% of senior management in *Fortune*'s 1,000 top companies are White men who may want to keep the status quo and use subtle discriminatory hiring practices to keep out women and people of color.

Actor-Observer Effect

John angrily explains that he got to his car to put more money in the meter just as the police officer was driving away. John adds that he's very responsible and the ticket was bad luck because he was only 45 seconds late. John says he got the ticket because the police officer was just being mean. John's explanation is a good example of the actor-observer effect (Malle, 2006).

The *actor-observer effect* refers to the tendency, when you are behaving (or acting), to attribute your own behavior to situational factors. However, when you are observing others, you attribute another's behavior to his or her personality traits or disposition.

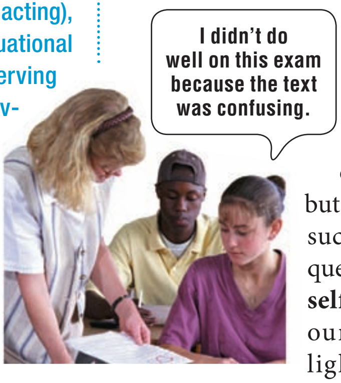
In the parking ticket example, John, the **actor,** attributes his getting the ticket to situational factors, just having bad luck, rather than to his own behavior, being late. In addition, John, the **observer,** explains that the police officer ticketed him because of a dispositional or personality factor—the officer was mean (Liberman et al., 2007). The actor-observer effect is very common. You can tell if you're making it by putting yourself in the position of the one you are observing (S. R. Wilson et al., 1997).

Self-Serving Bias

When we look for the causes of our own behaviors, such as why we received a good or bad grade on a test, we may make errors because of the self-serving bias (Fiedler, 2007; Mcallister et al., 2002).

The *self-serving bias* refers to explaining our successes by attributing them to our dispositions or personality traits and explaining our failures by attributing them to the situations.

The self-serving bias can be considered another part of the actor-observer effect. According to the self-serving bias, if you get an A on an exam, you tend to attribute your success to your personality traits or disposition, such as intelligence and perseverance. However, if you get a D on an exam, you tend to attribute your failure to the situation, such as a difficult test or unfair questions. Thus, according to the **self-serving bias,** we try to keep ourselves in the best possible light by making different and even opposite attributions, depending on whether we have performed well or poorly (Mcallister et al., 2002).



I didn't do well on this exam because the text was confusing.

The three errors that we just discussed show the need to be on guard so that these errors don't bias our attributions (Kenworthy & Miller, 2002).

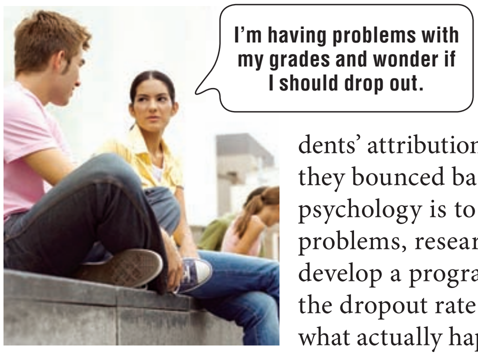
Although biased attributions can create problems, they can also be an advantage when they help us change our behaviors, as we'll discuss next.

Photo Credits: top, © Neville Elder/Corbis; bottom left and right, © PhotoDisc, Inc.

Can Changing Attributions Change Grades?

What problems do freshmen face?

Perhaps 20% of the students we counsel tell us about getting poor grades in their freshman year, and their reasons are very similar. Either they didn't develop good study habits in high school so they weren't academically prepared for college or they spent too much time partying or dealing with stressful personal, social, or financial difficulties. What is interesting is that some of the freshmen who got poor grades their first year were able to bounce back academically their second year, while others became discouraged and dropped out of college. Researchers discovered many differences in students' attributions—that is, how students explained why they bounced back or dropped out. Because one goal of psychology is to apply scientific findings to real-world problems, researchers used findings on attributions to develop a program for improving grades and lowering the dropout rate (T. D. Wilson & Linville, 1982). Here's what actually happened.



I'm having problems with my grades and wonder if I should drop out.

Kinds of Attributions

In explaining why a freshman is having academic problems, researchers may point to personal or dispositional attributions, such as the lack of necessary academic skills. Or researchers may point to external or situational attributions, such as pressures to party rather than study. Once a freshman has developed a pattern of getting poor grades, another question is whether the causes are permanent or temporary. For example, if freshmen attributed their academic problems to relatively permanent conditions, such as poor abilities, they would have little motivation and would expect little improvement. In addition, poor academic performance would make new students worried and anxious, which in turn would interfere with their ability to study.

However, if freshmen attributed their academic problems to temporary conditions, such as poor study habits, they could expect to improve if they developed better study skills. Researchers thought that if they could change students' attributions about poor academic performance and help them realize that it was a temporary rather than a permanent state, students could improve their grades.

Method: Changing Attributions

Researchers recruited freshmen who were having academic problems, such as scoring poorly on exams, not keeping up with assignments, and considering dropping out of college. These students were randomly divided into two different groups.

Students in the **experimental group** (attributions group) were given a number of procedures that changed their attributions about poor academic performance from a permanent cause to only a temporary condition. For example, students in the experimental group read a booklet about previous freshmen who had similar academic problems but showed improvement later in college. These subjects watched videotapes of previous students who described very convincingly how their grade point averages had risen after their freshman year. Next, these subjects were asked to write down all the reasons they could think of why grade point averages might improve after the freshman year.

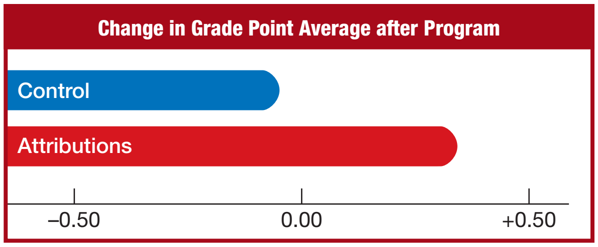
The other group of freshmen with academic problems did not receive any of this information and served as a **control group.**

I did terribly my freshman year but I got my act together and didn't drop out.

Results and Conclusions

Researchers found that changing students' attributions for poor academic performance from permanent to temporary had two significant positive effects.

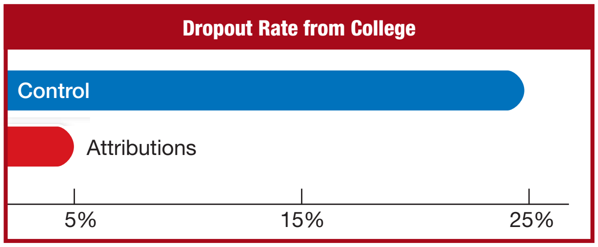
Change in Grade Point Average after Program



First, in the graph above, notice that freshmen who were told how to attribute their academic problems to temporary conditions (attributions group) had a significant improvement in grade point averages one year after the completion of this program.

Second, as shown in the graph below, only 5% of freshmen who changed their attributions for poor academic performance from permanent to temporary dropped out of college, while 25% of those in the control group dropped out.

Dropout Rate from College



From these data, researchers reached two important conclusions. First, it is possible to change students' attributions and expectations about academic performance. Second, changing students' attributions and expectations actually improved academic performance and reduced the dropout rate (T. D. Wilson & Linville, 1982). This study illustrates how social psychologists used the concept of attribution to solve a real-world problem (Covington, 2000).

Next, we'll discuss one of the most active areas of social cognition—forming and changing attitudes.

D. Attitudes

Definition

How much power do attitudes have?

The media regularly report on people's attitudes toward a wide range of hot topics, such as politics, religion, drug use, abortion, and sports. The concept of attitude, which in the 1930s was called the single most indispensable term in social psychology (Allport, 1935), continues to be one of the most studied concepts (Maio et al., 2006).

An *attitude* is any belief or opinion that includes an evaluation of some object, person, or event along a continuum from negative to positive and that predisposes us to act in a certain way toward that object, person, or event.

They believed God healed and prayer was the only treatment.

Attitudes can have a significant impact on behavior, as happened in the tragic death of an 11-year-old boy named Bo. An autopsy showed that Bo had died of complications from diabetes. After suffering painful symptoms for seven days, he went into a coma and died. At the time, he was 15–20 pounds underweight. Bo's parents were members of the Followers of Christ Church in Oregon, and they believed that prayer is a substitute for conventional medical treatment. The leader of the church had preached that God would heal and that anyone seeking worldly (medical) help was weak and lacked faith in God. Because of these attitudes, Bo received no medical treatment for his diabetes, which doctors said was an easily treatable problem. Records showed that as many as 25 children in the congregation had died in the past 20 years because they were treated with prayers instead of conventional medical help.

In most states, immunity from prosecution is granted to parents whose children sicken and die if the parents' religious beliefs permit only faith healing and not conventional medical treatment. Since Bo's death, Oregon changed its law so that parents who use religious beliefs to withhold medical treatment and allow their children to die of a treatable medical illness can face criminal charges (M. A. Hamilton, 2005; Reaves, 2001).

Bo's case, as well as our earlier discussion of suicide bombers (p. 471), is an example of attitudes that have the power to influence life-and-death decisions. Attitudes influence a wide range of behaviors and that is one reason billions of dollars are spent each year trying to measure and change attitudes and get people to buy certain products or vote for particular candidates. Attitudes, which can have very powerful influences on our lives, have three components.

Components of Attitudes

If we closely examined Bo's parents' attitudes toward faith healing and conventional medical treatment, we would find that attitudes influence their thoughts (cognitive component), feelings (affective component), and behaviors (behavioral component) (Huskinson & Haddock, 2006; Maio & Haddock, 2007).

1 Cognitive Component

Faith Heals
God's Will

Bo's parents did not approve of conventional medical treatment for their son because they believed that only prayers were needed since God does the healing (if that is His/Her will) and that seeking medical treatment indicated a lack of faith in God. The parents' beliefs illustrate the ***cognitive component*** of attitudes, which includes both thoughts and beliefs that are involved in evaluating some object, person, or idea.

An attitude's cognitive component can range from a very negative evaluation to a very positive one. For example, Bo's parents have a very positive belief in faith healing and a very negative evaluation of conventional medical treatment.

We have many attitudes that show our likes and dislikes, and often these attitudes are ***automatically*** triggered, without conscious thought on our part (Fabrigar et al., 2005).

2 Affective Component

Bo's parents were fearful of seeking conventional medical treatment because it meant going against God's will. The parents' fearful feelings illustrate the ***affective component*** of attitudes, which involves emotional feelings that can be weak or strong, positive or negative. For example, Bo's parents had strong positive feelings about using only prayers to treat their son's medical problem and strong fearful or negative feelings about seeking conventional medical treatment.

Researchers found that both ***beliefs*** and ***feelings*** are involved in how we form attitudes (Maio et al., 2006). For example, beliefs may be more important in forming political attitudes, such as whom to vote for, while feelings may be more important in forming dietary attitudes, such as deciding to eat dog or horse meat, which is considered very appetizing in some cultures.

3 Behavioral Component

The parents' positive attitude toward using prayer alone and their negative attitude toward seeking conventional medical treatment resulted in their not calling a medical doctor. The parents' refusal to call a medical doctor illustrates the ***behavioral component*** of attitudes, which involves performing or not performing some behavior.

In some cases, engaging in some behavior can influence the formation of an attitude (Maio et al., 2006). For example, having a good or bad experience in doing something (snowboarding, sky diving, using drugs, going to concerts) may result in a positive or negative attitude toward that activity.

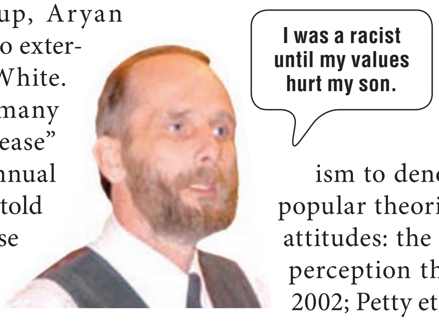
Attitudes can have weak to strong and positive to negative influences on our behaviors.

Changing attitudes is our next topic.

Attitude Change

What made a skinhead reform?

At one time, Floyd Cochran (right photo) was an out-and-out hatemonger who was a leader of the neo-Nazi group, Aryan Nation, in Idaho. His goal was to exterminate everyone who wasn't White. He constantly preached hatred, and he recruited many White youths to help him "spread the hate like a disease" (Cochran, 2007). Then, as he was preparing for the annual Hitler Youth Festival, a group of White supremacists told him that his 4-year-old son must be euthanized because he was born with a birth defect. Floyd found himself caught between his own years of preaching hate and members of Aryan Nation hating the son he loved. Floyd resolved his personal dilemma by renouncing his White supremacist values and abandoning the hate organizations. He now speaks out against hate and racism (Charmoli, 2006).



I was a racist until my values hurt my son.

Why did Floyd radically change his attitudes, from preaching hate and racism to denouncing these beliefs? We'll discuss two popular theories that explain why people change their attitudes: the theory of cognitive dissonance and self-perception theory (Harmon-Jones & Harmon Jones, 2002; Petty et al., 1997).

Cognitive Dissonance

After a group of White supremacists told him his son must be euthanized, Floyd's life became one big conflict. He had spent most of his adult life practicing racism and hate, but now his own personal values were causing him great anguish. Floyd found himself in the middle of a very troubling inconsistency, which Leon Festinger (1957) called cognitive dissonance.

Cognitive dissonance refers to a state of unpleasant psychological tension that motivates us to reduce our cognitive inconsistencies by making our beliefs more consistent with our behavior.

There are two main ways to reduce cognitive dissonance—that is, to make our beliefs and attitudes consistent with our behavior (Andersen et al., 2007).

Adding or changing beliefs. We can reduce cognitive dissonance by adding new beliefs or changing old beliefs and making them consistent with our behavior. In Floyd's case, cognitive dissonance was created by the conflict between being told the son he loved must be euthanized and his own racist and hate-filled beliefs. To decrease his cognitive dissonance, Floyd renounced his hateful beliefs so that his attitudes became consistent with his behavior, which was loving his son regardless of his birth defect.

Did he change his racist attitudes to resolve his cognitive dissonance?

Counterattitudinal behavior. Another way we can reduce cognitive dissonance is by engaging in opposite or counterattitudinal behavior (Leippe & Eisenstadt, 1994).

Counterattitudinal behavior involves taking a public position that runs counter to your private attitude.

A classic study by Festinger and Carlsmith (1959) illustrates how counterattitudinal behavior works. In this study, subjects were asked to do an extremely boring task, such as turning pegs in a board. At the end of the task, the experimenter asked the subjects to help out by telling the next group of subjects how interesting the task was. Subjects were asked to lie about the task and say it was interesting, which is engaging in counterattitudinal behavior. For saying the task was interesting, some subjects received $1 and some received $20. Sometime later, the original subjects were asked how much they had liked the boring task. A curious finding emerged. Subjects paid just $1 had a more favorable attitude about the boring task than those who were paid $20. That's because subjects paid $20 felt they were paid well for lying. Subjects paid $1 had no good reason for lying, and so, to resolve the cognitive dissonance between what they'd said (it was interesting) and what they felt (it was boring), they convinced themselves that the task was somewhat interesting. This shows that engaging in opposite or counterattitudinal behaviors can change attitudes. However, there's a different explanation for this experiment's results.

Self-Perception Theory

Perhaps subjects in the previous experiment came to believe their own lies (task was interesting) after engaging in counterattitudinal behavior not to reduce cognitive dissonance but because of changing their own self-perceptions.

Self-perception theory says that we first observe or perceive our own behavior and then, as a result, we change our attitudes.

Daryl Bem (1967), who developed self-perception theory, would explain that subjects paid only $1 for lying would recall their behavior and conclude that they would never have lied for only $1, so the task must have actually been interesting.

At first glance, cognitive dissonance theory and self-perception theory seem to be similar, since they both indicate that if we say something, it must be true. However, each theory points to a different reason. According to **cognitive dissonance theory,** the belief "if I said it, it must be true" occurs because we are trying to reduce the inconsistency in our beliefs and behaviors. In comparison, according to **self-perception theory,** concluding "if I said it, it must be true" simply reflects another way of explaining our own behaviors.

Did he change his racist attitudes because he spoke against racism?

Self-perception theory also challenges the traditional assumption that attitudes give rise to behavior. According to self-perception theory, behaviors give rise to attitudes. For example, after Floyd began speaking out against racism, his attitudes changed radically. Researchers have shown that behavior can influence attitudes (Leippe & Eisenstadt, 1994; Van Laar et al., 2005).

We may change our own attitudes in response to cognitive dissonance or self-perception. However, others are continually trying to change our attitudes through various forms of persuasion, our next topic.

D. Attitudes

Persuasion

Political candidates spend much of their time, energy, and money trying to persuade people to vote for them. What politicians have to decide is whether to use an intellectual or emotional appeal, how to appear honest, and what arguments to use. We'll begin with choosing between two different routes—central or peripheral (Maio & Haddock, 2007; Petty & Cacioppo, 1986).

Central Route

If the audience is interested in thinking about the real issues, a politician might best use the central route.

The ***central route for persuasion*** presents information with strong arguments, analyses, facts, and logic.

A political candidate using the central route for persuasion should present clear, detailed information about his or her views and accomplishments and should appear **honest** and **credible** by demonstrating knowledge and commitment to the issues and pointing out the opponents' records (Priester & Petty, 1995).

Politicians should choose the central route when they are trying to persuade voters who have a high need to know the facts and issues (Cacioppo & Petty, 1982). The central route for persuasion works with people who think about and analyze the issues. However, not all voters can be persuaded by the central route. For some, a peripheral route for persuasion is the better method.

I think logical arguments and hard facts work best.
I think emotional and personal appeals work best.

Peripheral Route

If the audience is more interested in the candidate's personality or image, a politician might seek votes using the peripheral route.

The ***peripheral route for persuasion*** emphasizes emotional appeal, focuses on personal traits, and generates positive feelings.

The peripheral route assumes that not all voters will spend the time and energy to digest or discuss the issues. Instead, some audiences are more interested in the candidate's ability to generate excitement and support by giving an **energetic** and **enthusiastic speech** (Priester & Petty, 1995). This route involves bands, banners, parties, and personal appearances, which build an inviting and exciting image and create a positive attitude toward the candidate. If audiences like the candidate's image, they will more likely agree with the candidate's views (Carlson, 1990).

The peripheral route is more concerned with style and image, and the central route is more concerned with substance and ideas. Researchers generally find that the central route produces more enduring results, while the peripheral route produces more transient results (Maio & Haddock, 2007; Perloff, 2002). Whether the central or peripheral route is used, a number of specific elements are important in persuasion.

Elements of Persuasion

Figuring out which elements are important in persuading people was begun in the 1950s by the Yale Communication Program, which is still considered one of the best models. This communication program identified a number of important elements in persuasion, including the source, message, and audience (Jacks & Cameron, 2003; Petty et al., 1997).

Source. One element in persuading someone to adopt your point of view involves the ***source of the message.*** We are more likely to believe sources who have a sense of authority, appear honest and trustworthy, have expertise and credibility, and are attractive and likable (Priester & Petty, 1995). For example, researchers found that good-looking TV fund-raisers generated nearly twice as many donations as did less attractive fund-raisers (Cialdini, 2001). The source element explains why national and cable TV newscasters and anchorpersons are usually physically attractive, likable, and believable.

Message. Another element of persuasion involves the ***content of the message.*** If the persuader is using the *central route,* the messages will contain convincing and understandable facts. If the facts are complicated, a written message is better than a spoken one (Chaiken & Eagly, 1976).

If the persuader is using the *peripheral route,* the messages should be designed to arouse emotion, sentiment, and loyalty. Television infomercials use the peripheral approach by having an attractive and likable demonstrator show how you will look or feel better by buying and using a particular product. However, using fearful messages to persuade people, such as showing blackened lungs to get smokers to quit, may not be effective because arousing fear may interfere with and distract people from hearing and taking precautionary measures to stop unhealthy practices (Ruiter et al., 2001).

Why is "The Daily Show" news host Jon Stewart worth millions?

One- versus two-sided messages. Some messages are better presented as **one-sided;** that is, you present only the message that you want accepted. Other messages are better presented as **two-sided;** that is, you include both the message and arguments against any potential disagreements (Jacks & Cameron, 2003). Thus, a persuader will select the best route (central or peripheral) and also the kind of message (one- or two-sided) (Jacks & Devine, 2000).

Audience. Another element of being an effective persuader involves knowing the ***characteristics of the audience.*** For example, audiences who are interested in facts are best persuaded using the central route, while audiences interested in personal traits are best persuaded using the peripheral route. If the audience is leaning toward the persuader, a one-sided message is best; if an audience is leaning away from the persuader, a two-sided message is best.

Thus, persuasion is a complicated process that involves the source's traits, using the central or peripheral route, and judging the audience's characteristics. Good persuaders may combine central and peripheral routes to win over the audience to their viewpoints (Cialdini, 2003).

Next, we'll discuss how cultures differ in their attitudes toward beauty, organ transplants, and women's rights.

E. Cultural Diversity: National Attitudes & Behaviors

Nigeria: Beauty Ideal

How do Nigerians judge beauty?

One reason the concept of attitude has been so dominant in social psychology is that our attitudes push or predispose us to think and behave in certain ways. What we often don't realize is how much our culture shapes our attitudes. For example, in the United States, the current attitude, especially among the middle and upper classes, is that for a woman to be attractive, she should be slender. This thin-is-beautiful attitude can pressure women to behave in certain ways, such as to constantly worry about their weight and to go on strict diets, which in some cases may result in eating disorders (Besenhoff, 2006; Hesse-Biber, 2007).

Beauty in Nigeria is to be heavy.

But thin is not always beautiful. For example, in Nigeria, Africa, a small group of young women were discussing who had the most beautiful body. They all agreed on Monique, age 15, because she was already heavy for her age and on her way to being very rotund. As one woman said, "I want to gain weight like Monique. I don't want to be thin" (Onishi, 2001, p. A4). Before getting married, young brides-to-be are sent to so-called fattening rooms, where the goal is to eat as much as they can to get fat and round so that the bride will be admired for her fullness.

However, in 2001, a slim, 6-foot-tall Nigerian became Miss World. This was the first time in 51 years that a Nigerian woman had won this title. Since most Nigerians over 40 consider beautiful women to have ample backsides and bosoms, they thought the new trim Miss World was not particularly beautiful. But many of the younger Nigerians took notice of Miss World's dimensions and have begun to change their attitudes and adopt Western beauty standards that value being slim (Onishi, 2002). This difference in beauty attitudes between America and Africa clearly shows how cultural values not only shape attitudes but also predispose us to behave in certain ways.

A different debate over attitudes is going on in Japan.

Japan: Organ Transplants

What is the Japanese attitude on death?

Miss Wakana Kume, who lives in Japan, was going to die unless she received a liver transplant. However, since 1968, it has been illegal in Japan to transplant organs from donors who are brain-dead. Like all Japanese, Miss Kume grew up with the attitude that brain-dead was not really dead, so she was very reluctant to get a transplant from a brain-dead donor. But because of the seriousness of her condition, Miss Kume flew to Australia, where she underwent a liver transplant. In a very real sense, Miss Kume engaged in counterattitudinal behavior by doing a behavior opposite of what she believed—getting a transplanted organ. Since her life-saving transplant, Miss Kume has changed her attitude toward organ transplants and now approves of them. This is a real example of changing attitudes by engaging in counterattitudinal behavior.

Organ transplants are now more common in Japan.

The reason there were about 24,000 organ transplants in the United States in 1997 but none in Japan is that cultures have different definitions of death. In the United States, death is defined as brain death—when a person's brain no longer shows electrical activity, even though the heart is still beating. In Japan, however, death was defined as the moment a person's heart stops beating, and donor organs could be removed only after the heart stops. But to be useful, donor organs must be removed when a person's heart is still beating. In 1997, Japan passed a law allowing organs to be donated by an individual who is brain-dead under certain strict conditions. Because brain death has been legalized in Japan, organ transplants are now possible and many Japanese have changed their attitudes toward death and accept organ transplants (Ling & Ming, 2006; McNeill & Coonan, 2006).

A debate over attitudes and behaviors is also going on in Egypt.

Egypt: Women's Rights

How do Egyptians view women?

Since the early 1900s, Egyptian women have been fighting for their sexual, political, and legal rights in a society that is dominated by Muslim religious principles, which grant women few rights. For example, while women are supposed to wear veils to preserve their dignity, a husband may strike his wife as long as he doesn't hit her in the face and hits lightly. Many women are not given birth certificates, which means that they cannot vote, get a passport, or go to court. Although genital cutting (p. 346) is illegal in Egypt, virtually all women in certain areas have been subjected to it.

Egyptian women are learning to fight back.

Egyptian women are now fighting for more rights. Some women are taking martial arts training to learn to fight off assailants (photo below). The rising problem of sexual harassment of Egyptian women motivates these women to learn self-defense methods (Fraser, 2009; A. Johnson, 2009). Women are also fighting to not wear veils in public and to get good jobs. However, they are having limited success because these traditional attitudes are backed by powerful social forces, including political, cultural, and religious institutions (Ezzat, 2004; Tolson, 2003). In getting Egyptians to change their attitudes toward women, advocates will need to use trustworthy and honest sources, present one- or two-sided arguments, and, depending on the audience, use the central or the peripheral route for persuasion.

Next, we'll learn how persuasion involves social forces.

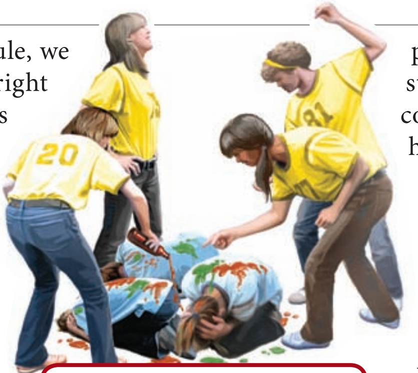
F. Social & Group Influences

Conformity

Why did the seniors haze the juniors?

At the beginning of this module, we discussed a hazing incident (right picture) in which senior girls beat, slapped, and kicked junior girls, hit them with buckets, and smeared them with blood, fish guts, mud, and feces. Five of the junior girls ended up in the hospital, some requiring stitches. Especially troubling was that these students, who came from a well-to-do Chicago suburb, attended a very good high school, and went on to attend college, would engage in such ugly and violent hazing behaviors (L. Black & Flynn, 2003).



Hazing has changed to include potentially dangerous behaviors.

Hazing may be part of a group's initiation ritual during which individuals are subjected to a variety of behaviors that range from humiliating and unpleasant to potentially dangerous both physically and psychologically.

In the United States, about 48% of high school and college students involved in a group activity (clubs, sports) report being hazed, and nearly everyone who gets hazed is humiliated (Lipkins, 2006). When students were asked why they agreed to be hazed, many answered they did so because it made them feel part of the group (N. C. Hoover & Pollard, 2000). "Going along" with the group is an example of conformity (J. M. Levine & Kerr, 2007).

Conformity refers to any behavior you perform because of group pressure, even though that pressure might not involve direct requests.

Normally, most students (and most of us) would never conform or agree to be publicly humiliated. Yet, reacting to strong group pressures, 48% of high school and college students who participate in group activities conform and agree to be hazed, which means humiliation and possible injury.

There are many examples of conforming, such as wearing clothes that are in style, adopting the "in" slang phrases, and buying the currently popular products. A recent example of conformity in the United States began in the late 1990s, when it became popular to carry your own bottle of water. It is now nearly an $11-billion-a-year business in the United States alone (Castellitto, 2008). This practice has grown in popularity, fueled by the idea that bottled water was pure but also that it was healthy and perhaps necessary to drink at least "8 glasses of water a day." When a researcher looked into the evidence behind "8 glasses a day," he discovered that this idea was based on opinion, not any scientific evidence. The researcher concluded that it's safe for healthy people to drink considerably less, since we obtain fluids from a variety of foods and beverages (G. Reynolds, 2006). The water bottle phenomenon is a modern example of conformity and, as one researcher put it, perhaps a new kind of adult security blanket (Valtin, 2002).

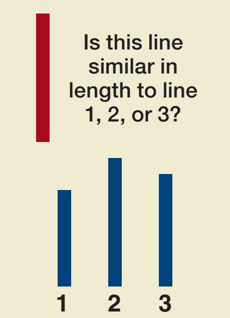
We'll discuss group pressures and why people conform and obey, beginning with a classic experiment in social psychology.

Asch's Experiment

A classic experiment is one that causes us to change the way we think about something—in this case, how social pressures can influence conformity (Blakeslee, 2005; Stasser & Dietz-Uhler, 2003). Solomon Asch's (1958) classic experiment showed very clearly how an individual can be pressured to conform to a group's standards. As we describe Asch's experiment, imagine that you are a subject and guess how you might have behaved.

Procedure

You are seated at a round table with five others and have been told that you are taking part in a visual perception experiment. Your group is shown a straight line and then is instructed to look at three more lines of different lengths and pick out the line equal in length to the original one. The three choices are different enough that it is not hard to pick out the correct one. Each person at the round table identifies his or her choice out loud, with you answering next to last. When you are ready to answer, you will have heard four others state their opinions. What you do not know is that these four other people are the experimenter's accomplices. On certain trials, they will answer correctly, making you feel your choice is right. On other trials, they will deliberately answer incorrectly, much to your surprise. In these cases you will have heard four identical incorrect answers before it is your turn to answer. You will almost certainly feel some group pressure to conform to the others' opinion. Will you give in?



These are the kinds of lines used in Asch's study on conformity.

Results

Out of 50 subjects in Asch's experiment, 75% conformed on some of the trials, but no one conformed on all the trials; 25% never conformed. These data indicate that the desire to have your attitudes and behaviors match those of others in a group can be a powerful force.

A recent study used fMRI brain scans (p. 70) to record brain activity during an Asch-type research design to examine whether social pressure changes people's perceptions or people who give in to the group do so knowing their answers are wrong (Berns, 2005). Results showed that when people went along with the group on wrong answers, activity in the brain area associated with spatial awareness and perception increased. But, when people resisted group pressure and gave a correct answer, activity in the brain area associated with strong emotions increased. These results suggest that information provided by others may actually change what we see and that going against the group can be a very unpleasant experience.

Asch's study is considered a classic because it was the first to clearly show that group pressures can influence conformity. However, we may conform publicly but disagree privately, and this is an example of compliance.

Figure/Text Credit: Asch study based on "Effects of Group Pressure Upon Modification and Distortion of Judgements," by Solomon Asch, 1958. In E. Maccoby, T. M. Newcomb & E. L. Hartley (Eds.), *Readings in Social Psychology* (3rd Ed.). Holt, Rinehart & Winston.

Compliance

Were the subjects just pretending?

One interpretation of Asch's data is that subjects were not really changing their beliefs but rather just pretending to go along with the group. For example, when subjects in Asch's experiment privately recorded their answers, conforming drastically declined. This decline indicated that subjects were conforming but not really changing their beliefs, which is one kind of compliance.

Compliance is a kind of conformity in which we give in to social pressure in our public responses but do not change our private beliefs.

For example, you may conform to your instructor's suggestions on rewriting a paper although you do not agree with the suggestions. In this case, you would be complying with someone in authority.

One particular technique of compliance is used by salespeople, who know that if they get the customer to comply with a small request (get a foot in the door), the customer is more likely to comply with a later request to buy the product (Cialdini & Goldstein, 2004).

Salespeople use the foot-in-the-door technique.

The ***foot-in-the-door technique*** refers to the technique of starting with a little request to gain eventual compliance with a later request.

A common example of the foot-in-the-door technique is telemarketers who first get you to answer a simple question such as "How are you today?" so that you'll stay on the phone and answer their other questions. The foot-in-the-door technique is one successful way to obtain compliance (Rodafinos et al., 2005).

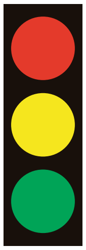
If you are officially or formally asked to comply with a request, such as "Take a test on Friday," your compliance is called obedience.

Obedience

Do you run red lights?

When it comes to signs, laws, rules, and regulations, such as speed limits, traffic lights, smoking restrictions, parental requests, instructors' assignments, and doctors' orders, people differ in what they choose to obey.

Obedience refers to performing some behavior in response to an order given by someone in a position of power or authority.



A serious problem in states across the country is drivers who run red lights and cause accidents. To increase obedience, cameras automatically take photos of drivers who run red lights, and these drivers are mailed tickets with expensive fines ($270 in California). Here's a case of using punishment to decrease accidents by increasing obedience (up to 96% reduction in running red lights) (Copeland, 2007).

Most of us obey orders, rules, and regulations that are for the general good. But what if the orders or rules are cruel or immoral?

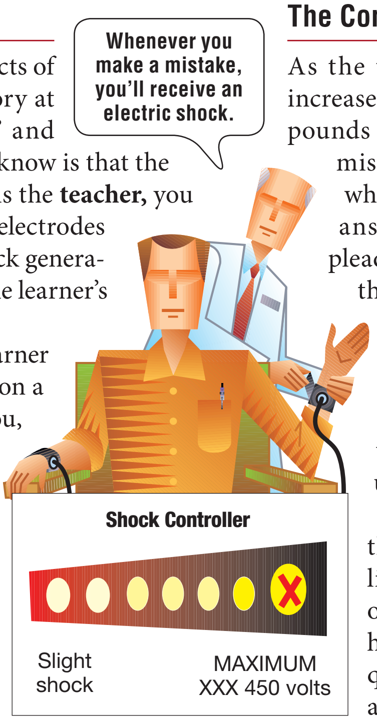
Milgram's Experiment

Stanley Milgram's (1963) experiment on obedience is a classic experiment in social psychology because it was the first to study whether people would obey commands that were clearly inhumane and immoral (A. Miller, 2005). As we describe this famous experiment, imagine being the "teacher" and consider whether you would have obeyed the experimenter's commands.

The Setup

Imagine that you have volunteered for a study on the effects of punishment on learning. After arriving in the laboratory at Yale University, you are selected to be the "teacher" and another volunteer is to be the "learner." What you don't know is that the **learner** is actually an accomplice of the experimenter. As the **teacher,** you watch the learner being strapped into a chair and having electrodes placed on his wrists. The electrodes are attached to a shock generator in the next room. You and the researcher then leave the learner's room, close the door, and go into an adjoining room.

The researcher gives you a list of questions to ask the learner over an intercom, and the learner is to signal his answer on a panel of lights in front of you. For each wrong answer, you, the teacher, are to **shock the learner** and to increase the intensity of the shock by 15 volts for each succeeding wrong answer. In front of you is the shock machine, with 30 separate switches that indicate increasing intensities. The first switch is marked "15 volts. Slight shock," and the last switch is marked "XXX 450 volts. Danger: Severe shock." You begin to ask the learner questions, and as he misses them, you administer stronger and stronger shocks.



Whenever you make a mistake, you'll receive an electric shock.
Shock Controller
X
Slight shock
MAXIMUM XXX 450 volts

The Conflict

As the teacher, you give the learner shocks that increase in intensity up to 300 volts, when the learner pounds on the wall. You continue and after the next miss, you give the learner a 315-volt shock, after which the learner pounds on the wall and stops answering any more questions. Although you plead with the researcher to stop the experiment, the researcher explains that, as the teacher, you are to continue asking questions and shocking the learner for incorrect answers. Even though the learner has pounded on the wall and stopped answering questions after a 315-volt shock, would you continue the procedure until you deliver the XXX 450 volts?

What you, the teacher, didn't know is that the learner is part of the experiment and acts like being shocked but never received a single one. The teacher was misled into believing that he or she was really shocking the learner. The question was whether a teacher would continue and deliver the maximum shock.

F. Social & Group Influences

Milgram's Results

How many obeyed?

The scary question was how many "teachers" (subjects) would deliver the maximum intensity shock to the "learner."

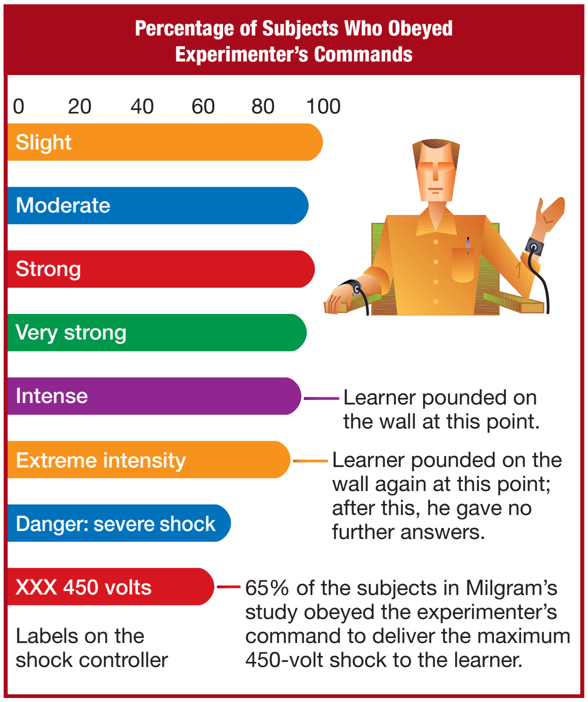
0.12% When psychiatrists were asked to predict how many subjects would deliver the full range of shocks, including the last 450 volts, they estimated that only 0.12% of the subjects would do so.

2% When members of the general public were asked the same question, they predicted that only 2% of the subjects would deliver the maximum 450 volts.

65% To the surprise and dismay of many, including Milgram, 65% of the subjects (no difference between males and females) delivered the full range of shocks, including the final XXX 450 volts.

When Stanley Milgram conducted these studies on obedience in the early 1960s, they demonstrated that people will obey inhumane orders simply because they are told to do so. This kind of unthinking obedience to immoral commands was something that psychiatrists, members of the general population, and Milgram had not predicted. Milgram (1974) repeated variations of this experiment many times and obtained similar results. Additionally, Milgram's experiment was repeated in various parts of the world with similar results (T. Blass, 2000).

The results of these experiments helped answer a question people had asked since World War II: Why had Germans obeyed Hitler's commands? More recently, the results of Milgram's experiments can help answer why U.S. soldiers tortured, raped, and murdered prisoners held in Abu Ghraib. And why do students follow group leaders and engage in hazing, with sometimes dangerous consequences? According to Milgram's experiments, social situations that involve power and authority greatly increase obedience to the point that a large percentage of people will obey orders even if they are clearly unreasonable and inhumane.



Percentage of Subjects Who Obeyed Experimenter's Commands

Learner pounded on the wall at this point.

Learner pounded on the wall again at this point; after this, he gave no further answers.

65% of the subjects in Milgram's study obeyed the experimenter's command to deliver the maximum 450-volt shock to the learner.

Labels on the shock controller

Why Do People Obey?

Psychologists have suggested several reasons that 65% of the subjects in Milgram's experiment agreed to deliver the maximum shock to learners. Perhaps the major reason is that people have learned to follow the orders of **authority figures,** whether they are religious leaders, army commanders, doctors, scientists, or parents. However, people are more likely to obey authority figures when they are present. In one of his follow-up studies, Milgram (1974) found that when subjects received their instructions over the telephone, they were more likely to defy authority than when they received their instructions in person. This also explains why patients don't follow doctors' orders once they leave their offices.

People also obey because they have **learned to follow orders** in their daily lives, whether in traffic, on the job, or in personal interactions. However, people are more likely to obey if an authority figure is present (police officer, boss, or parent). What Milgram's study showed was that blind obedience to unreasonable authority or inhumane orders is more likely than we think.

Were Milgram's Experiments Ethical?

Although the Milgram experiments provided important information about obedience, the study could not be conducted under today's research guidelines. As we discussed (p. 40), all experiments today, especially those with the potential for causing psychological or physical harm, are carefully screened by research committees, a practice that did not exist at the time of Milgram's research. When there is a possibility of an experiment causing **psychological harm,** the researchers must propose ways to eliminate or counteract the potential harmful effects. This is usually done by thoroughly debriefing the subjects.

Debriefing **occurs after an experimental procedure and involves explaining the purpose and method of the experiment, asking the subjects their feelings about being in the experiment, and helping the subjects deal with possible doubts or guilt arising from their behaviors in the experiment.**

Although Milgram's subjects were debriefed, critics doubted that the question of whether any psychological harm had been done to the subjects was resolved. Because the potential for psychological harm to the subjects was so great in Milgram's studies, any related research had to pass very strict ethical standards. Jerry Burger, a researcher at Santa Clara University, designed a study replicating as much of Milgram's study as possible while complying with current ethical standards (Burger, 2007, 2009). Subjects were an ethnically diverse group of 18 men and 22 women. The setup and conflict procedures were mostly the same as in Milgram's study except that, due to ethical standards, the maximum shock the subjects could administer was 150 volts, compared to the 450 volts used in Milgram's study. Results showed that 70% of subjects (equal percentages of men and women) pressed the button for the highest, most dangerous shock possible (150 volts). Thus, ordinary people, even in today's society, are capable of hurting others despite hearing the person begging them to stop, as long as they are ordered by an authority figure to do so.

Next, we'll turn to another interesting question: Why do people help?

Helping: Prosocial Behavior

Would you risk your life to help a stranger?

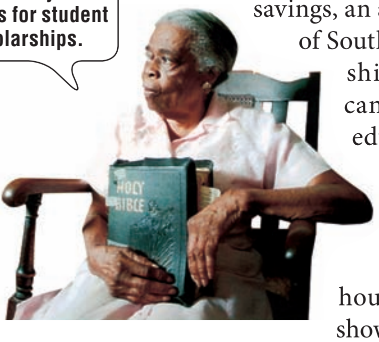
While Wesley Autrey was waiting for the subway in New York City, he saw a man suffering from a seizure fall onto the tracks. A train was rapidly approaching the station and, knowing the man would be killed in only seconds, Wesley immediately jumped onto the tracks and covered the man with his body. The train passed over their bodies leaving only inches to spare. The train came so close to Wesley's body that it left grease marks on his hat (C. Buckley, 2007; Trump, 2007). Wesley's quick, heroic action is an example of helping, or prosocial behavior.

Prosocial behavior, which is also called ***helping,*** is any behavior that benefits others or has positive social consequences.

In our society, professionals, such as paramedics, are trained and paid to provide help. However, in Wesley's case, he was the only onlooker who risked his life to save a seizing man who had no possibility of surviving on his own. Wesley's helping may be described as altruistic, since he expected no external reward.

Altruism is one form of helping or doing something, often at a cost or risk, for reasons other than the expectation of a material or social reward.

Altruistic people often do things that touch our hearts. Consider 87-year-old Osceola McCarty (photo below), who hand-washed clothes most of her life for grateful clients. When she finally retired at age 86, she donated most of her life savings, an amazing $150,000, to the University of Southern Mississippi to finance scholarships for the area's African American students. "I want them to have an education," said McCarty, who never married and has no children of her own. "I had to work hard all my life. They can have the chance that I didn't have" (Plummer & Ridenhour, 1995, p. 40). As these examples show, some people help in emergencies, and others help by donating time or money. What motivates people to help others?



I donated most of my life savings for student scholarships.

Why People Help

Would you help?

Why did Osceola McCarty, who spent her life washing clothes, donate most of her hard-earned life savings to finance scholarships instead of using her savings to make her retirement more comfortable? Researchers suggest at least three different motivations—empathy, personal distress, and norms and values—to explain why people, like McCarty, are altruistic and help others without thought of rewards (Batson, 1998; Schroeder et al., 1995):

- We may help because we feel **empathy**—that is, we identify with what the victim must be going through. Osceola McCarty may have donated her life savings for scholarships because she felt empathy for other African American students.
- We may help because we feel **personal distress**—that is, we have feelings of fear, alarm, or disgust from seeing a victim in need. Osceola said that she didn't want other young African American people to have to go through the hard times that she had faced.
- We may help because of our **norms and values**—that is, we may feel morally bound or socially responsible to help those in need.

Researchers have combined these three motivations along with several other ideas to construct two different theories of why people come out of a crowd and help perfect strangers. We can use these two theories to explain why Wesley was the only onlooker at the subway station who dared to jump on the tracks and risk his life to save that of another man.

Decision-Stage Model

Wesley may have decided to help after going through five stages, which involved making five different decisions.

The ***decision-stage model of helping*** says that you go through five stages in deciding to help: (1) you notice the situation; (2) you interpret it as one in which help is needed; (3) you assume personal responsibility; (4) you choose a form of assistance; and (5) you carry out that assistance.

Why did only Wesley Autrey from a crowd of people risk his life to save the life of another man?

According to the decision-stage model, Wesley helped because he went through all five stages. Most onlookers stopped at stage 3 and decided it was not their responsibility, so they did not help. This model explains that people may recognize a situation as an emergency (stages 1 and 2) yet fail to help because they do not take personal responsibility for the situation (Latané & Darley, 1970).

Arousal-Cost-Reward Model

Wesley also may have helped the seizing man because he thought about the costs and rewards.

The ***arousal-cost-reward model of helping*** says that we make decisions to help by calculating the costs and rewards of helping.

For example, seeing an accident may cause you to be unpleasantly and emotionally **aroused,** which you wish to reduce. In deciding how to reduce these unpleasant feelings, you calculate the **costs** and **rewards** of helping. For example, those who decided not to help may have felt that the costs of helping, such as getting involved in a potentially dangerous situation, outweighed the rewards (Piliavin et al., 1982).

According to these two models, Wesley experienced five stages (five decisions) and then decided to help, or Wesley possibly considered the costs and rewards of reducing his unpleasant emotional feelings and then decided to help. Although the arousal-cost-reward model and the decision-stage model focus on different factors, they are not mutually exclusive.

Next, we'll explain how social forces influence people in groups.

F. Social & Group Influences

Group Dynamics

What happens in groups?

When you're with family, friends, or co-workers, you may or may not be aware of the numerous group influences that can greatly change how you think, feel, and behave.

Groups are collections of two or more people who interact, share some common idea, goal, or purpose, and influence how their members think and behave.

To illustrate the powerful influences of groups, we'll describe the case of Dennis Jay, who almost died in a drunken coma and later heard that his fraternity brothers had lied about the initiation that had almost killed him.

Group Cohesion and Norms

My fraternity brothers lied about why I was in a coma.

As a pledge at a fraternity initiation party, Dennis Jay and 19 others submitted to hazing: They were forced to drink from a "beer bong," a funnel into which beer was poured; the beer ran down a plastic hose placed in the mouth (left photo). The rule was that once you threw up, you could stop drinking from the beer bong. Because he did not throw up, Jay was given straight shots of whiskey until he fell on his face. By the time his frat brothers got Jay to the hospital, he was in a coma and barely breathing. His blood alcohol content was 0.48, and a level of 0.50 is usually fatal (legally drunk in many states is 0.08).

At first, Jay refused to describe what happened because he wanted to be loyal to his fraternity. Then he heard that the fraternity brothers had lied and said that he had stumbled drunk into their frat house and that they had brought him to the emergency ward just to help out. The fraternity brothers' lies made Jay angry, and he told the truth (Grogan et al., 1993). As discussed earlier, one reason individuals like Jay endure harmful and humiliating hazing rites is because they wish to become a member of a desired group.

Social psychologists would explain that the fraternity lied about what happened to Jay because of two powerful group influences: group cohesion and group norms.

Group cohesion is group togetherness, which is determined by how much group members perceive that they share common attributes.

One reason many groups have some form of initiation rites and rituals is to have all members share a common experience and thus increase group cohesion.

Group norms are the formal or informal rules about how group members should behave.

Group norms, written or unwritten, can exert powerful influences, both good and bad, on group members' behaviors (Hewstone et al., 2002). For example, because of powerful group norms to stick together to preserve their group, these fraternity members were willing to lie about what really happened to Jay.

Group Membership

In his hierarchy of human needs (see p. 333), humanistic psychologist Abraham Maslow identified *the need for love and belonging* as fundamental to human happiness (Maslow, 1970). One way to satisfy this social need is by joining a group, which helps individuals feel a sense of belonging, friendship, and support. The need for belonging carries into adulthood as individuals join various community and business organizations. According to Maslow's theory, the social need to belong points to a **motivational reason** for joining groups. At about the same time Maslow published his work on the hierarchy of motivation, Leon Festinger (1954) offered another reason for joining groups, based on the social comparison theory.

Social comparison theory says that we are driven to compare ourselves to others who are similar to us, so that we can measure the correctness of our attitudes and beliefs. According to Festinger, this drive to compare ourselves motivates us to join groups.

According to Festinger's theory, the drive to compare and judge our attitudes and beliefs against those of others who are similar to us points to a **cognitive reason** for joining groups.

An additional reason for forming groups is that we can accomplish things in groups that we simply cannot do alone. For example, students form study groups because they want academic help, social support, and motivation. However, there are two kinds of study groups, each with different goals: task-oriented and socially oriented groups (Burn, 2004).

In a ***task-oriented group,*** the members have specific duties to complete.

In a ***socially oriented group,*** the members are primarily concerned about fostering and maintaining social relationships among the members of the group.

For example, a task-oriented group helps members achieve certain academic, business, political, or career goals, while a socially oriented group primarily provides a source of friends, fun activities, and social support.

A group of young Mormons in training

Group membership can have a powerful influence on many social interactions, such as deciding with whom to socialize, whom to discriminate against, which principles to follow, and whom to battle, psychologically and physically (Simon & Sturmer, 2003). An example of how group membership influences members' views and behaviors occurs during national elections, when Republicans and Democrats wage hard-fought political and personal battles for money, votes, and power.

Next, we'll discuss how groups and crowds can influence our behaviors.

Photo Credits: left, © 1993 Taro Yamasaki; right, Jim LoScalzo/*U.S. News & World Report*

Behavior in Crowds

How do you behave in a crowd?

You may not notice, but being in a crowd can cause you to think and behave differently than when you're alone.

A ***crowd,*** which is a large group of persons who are usually strangers, can facilitate or inhibit certain behaviors.

For example, we'll discuss how being in a crowd can increase or decrease personal performance, encourage individuals to engage in antisocial behaviors, such as riots, or cause individuals to refuse to help to someone in need.

Facilitation and Inhibition

Performing before a large crowd can facilitate or inhibit behaviors.

If a runner has a history of successful competition, he may turn in a better performance in front of a large crowd as a result of social facilitation.

Social facilitation is an increase in performance in the presence of a crowd.

In contrast, if a runner has a spotty history in competition, he may turn in a worse performance in front of a large crowd because of social inhibition.

Social inhibition is a decrease in performance in the presence of a crowd.

Whether we show facilitation or inhibition depends partly on our previous experience. Generally, the presence of others will facilitate well-learned, simple, or reflexive responses but will inhibit new, unusual, or complex responses. An example of social facilitation occurs during championship games when a player is awarded the title of "most valuable player." An example of social inhibition also occurs during championship games when a star player, who is expected to do great, instead feels anxiety about performing and plays poorly or "chokes" (Baumeister, 1995). Thus, the presence of a crowd can either facilitate or inhibit behaviors, depending on the situation (Burn, 2004).

Deindividuation in Crowds

During the Los Angeles riots in the early 1990s, people were arrested for looting, setting fires, and beating others. Individuals in a crowd are more likely to commit such antisocial acts because being in a crowd conceals the person's identity, a process called deindividuation.

Deindividuation refers to the increased tendency for subjects to behave irrationally or perform antisocial behaviors when there is less chance of being personally identified.

Looting is more likely to occur in a crowd because of deindividuation.

Researchers believe deindividuation occurs because being in a crowd gives individuals anonymity and reduces guilt and self-awareness, so that people are less controlled by internal standards and more willing to engage in deviant or antisocial roles (Silke, 2003; Zimbardo, 1970). Support for this explanation of deindividuation comes from competitive sporting events in which spectators turned into violent individuals (Postmes & Spears, 1998).

Another situation where deindividuation occurs and people feel anonymous is on the Internet. For instance, teens are willing to disclose sexual information when their anonymity is ensured on the Internet (Chiou, 2006).

The Bystander Effect

As a person lies unconscious on a city sidewalk, dozens or hundreds of people may walk by without helping. There are several reasons no one stops to help, including fear of the person's reactions, inexperience with providing help, and the bystander effect.

The ***bystander effect*** says that an individual may feel inhibited from taking some action because of the presence of others.

Data from over 50 studies indicate that 75% of people offer assistance when alone, but fewer than 53% do so when in a group (Latané & Nida, 1981). There are two explanations for the bystander effect.

The ***informational influence theory*** says that we use the reactions of others to judge the seriousness of the situation.

If other bystanders are taking no action, we conclude that no emergency exists and we do nothing to offer help or aid (Burn, 2004).

The ***diffusion of responsibility theory*** says that, in the presence of others, individuals feel less personal responsibility and are less likely to take action in a situation where help is required (Latané, 1981).

Recent survey results report that 77% of Americans want to help victims of disasters such as hurricanes and earthquakes, but when it comes to volunteering, many will not because they believe the whole country is already helping (Marchetti & Bunte, 2006). Thus, an individual may feel less responsibility to offer help or aid.

The presence of others also influences how we make decisions, which we'll examine next.

Just being in the presence of other strangers can inhibit an individual from helping someone in need.

F. Social & Group Influences

Group Decisions

Does being in a group affect thinking?

All of us have been in groups—families, fraternities, sororities, various social or business clubs. What you may not realize is that being in a group creates social pressures that influence how you think and make decisions. We'll discuss two interesting factors in making decisions: group polarization and groupthink.

Group Polarization

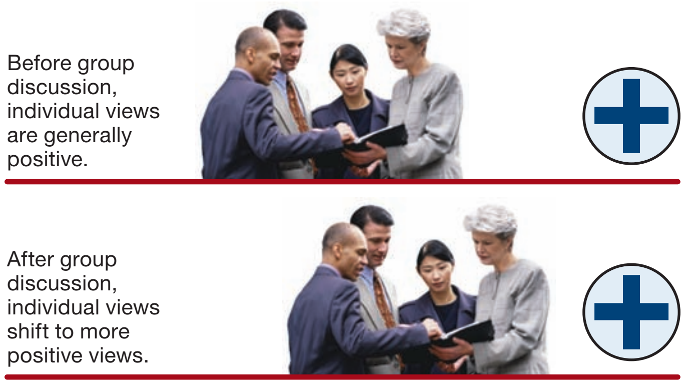
Imagine that a young lawyer is trying to decide between two job offers. The first offer is from a large, well-established firm that promises more security, financial opportunities, and prestige. However, it has a poor record as an equal opportunity employer of women and currently has no women partners. The second offer is from a small, recently established firm that can promise little security or prestige. However, this firm is doing well and has an excellent record in promoting women as partners. Which offer should the lawyer accept? Using dilemmas such as this, researchers compared the recommendations from individuals in a group with those made by the group after it had engaged in discussion (Gigone & Hastie, 1997; Pruitt, 1971). Group discussions change individuals' judgments, such as when a group urges a more risky recommendation than do individuals. This phenomenon became known as the **risky shift.**

Researchers later discovered that the direction of a group's risky shift depends on how conservative or liberal the group was to begin with. If a group's members are initially more conservative, group discussion will shift its decision to an even more conservative one. If a group's members are initially more liberal, group discussion will shift its decision to an even more liberal one.

The group's shift to a more extreme position is called group polarization (Fiedler, 2007).

Group polarization is a phenomenon in which group discussion reinforces the majority's point of view and shifts that view to a more extreme position.

Group Polarization



Before group discussion, individual views are generally positive.
After group discussion, individual views shift to more positive views.

Whether this group polarization (figure above) is in a liberal or conservative direction depends on the initial leanings of the group's members. Researchers also found that the more the group repeated each other's arguments, the more polarized the group became (Burn, 2004). Thus, repetition of the same arguments resulted in stronger formation of attitudes and more group polarization.

Groupthink

In the early 1960s, President John F. Kennedy took the world to the brink of nuclear war when he ordered the invasion of Cuba. This invasion, which occurred at the Bay of Pigs, was a terrible decision and a well-remembered failure. Researchers have analyzed group decision-making processes involved in bad decisions, such as the Bay of Pigs, the escalation of war in Vietnam, the Watergate cover-up, and the *Challenger* disaster, as well as flawed group decisions in business and other organizations. One reason that groups made bad decisions in the above examples is a phenomenon called groupthink (Janis, 1989; Vallacher & Nowak, 2007).

Groupthink

What's most important is that we stick together.

Groupthink refers to a group making bad decisions because the group is more concerned about reaching agreement and sticking together than gathering the relevant information and considering all the alternatives (right figure).

Groupthink. According to psychologist Irving Janis (1989), groupthink has a number of clearly defined characteristics: Discussions are limited, few alternatives are presented, and there is increased pressure to conform. For example, the group usually has a member that Janis calls a ***mindguard,*** whose job is to discourage ideas that might be a threat to the group's unity. In addition, groupthink results in viewing the world in very simple terms: There is the **ingroup,** which includes only the immediate members of the group, versus the **outgroup,** which includes everyone who is not a part of the group. When a group adopts the ingroup–outgroup attitude and mentality, the result is that it strengthens groupthink by emphasizing the protection of the group's members over making the best decisions.

Avoiding groupthink. One authority on groupthink recommends using a method, called vigilant decision making, that helps a group avoid falling into groupthink and thus leads to better decisions (Janis, 1989). Major elements of ***vigilant decision making*** include the following: doing a thorough, open, and unbiased information search; evaluating as many alternative ideas as possible; and having an impartial leader who allows the members to freely and openly express differing opinions without being criticized or being considered a threat to the group. Researchers found that the vigilant decision-making method does result in better and more successful group decisions, although it is criticized for being very time-consuming (Burn, 2004).

After the Concept Review, we'll learn about how our social interactions affect our brain.

Photo Credits: © PhotoDisc, Inc.

Concept Review

1. A broad field that studies how our thoughts, feelings, perceptions, and behaviors are influenced by interactions with others is called (a) ________________. A major branch of this field that studies how people perceive, retrieve, and interpret information about social interactions is called (b) ________________.

2. Making judgments about the traits of others through social interactions and gaining knowledge from our social perceptions are called ________________.

3. Widely held beliefs that people have certain traits because they belong to a particular group are known as (a) ________________. An unfair, biased, or intolerant attitude toward another group of people is called (b) ________________. Specific unfair behaviors exhibited toward members of a group are known as (c) ________________.

4. Cognitive structures that represent an organized collection of knowledge about people, events, and concepts are called ________________. They influence what we perceive and remember and how we behave.

5. The process by which we look for causes to explain a person's behavior is known as (a) ________________. If we attribute behavior to the internal characteristics of a person, we are attributing the behavior to the person's (b) ________________. If we attribute behavior to the external circumstances or context of that behavior, we are attributing the behavior to the (c) ________________.

6. If we attribute the cause of a behavior to a person's disposition and overlook the demands of the environment or situation, we are committing the (a) ________________ error. If we attribute our own behavior to situational factors but the behaviors of others to their disposition, we are committing the (b) ________________ effect. If we attribute success to our disposition and failure to the situation, we are using the (c) ________________ bias.

7. Beliefs or opinions that include a positive or negative evaluation of some target (object, person, or event) and that predispose us to act in a certain way toward the target are called ________________.

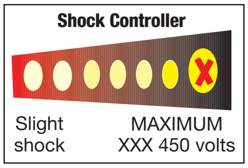
8. There are two different theories about why we change our attitudes. One theory says that experiencing cognitive inconsistencies produces psychological tension that we try to reduce by making our beliefs more consistent. This is called (a) ________________ theory. If we take a public position that is counter to our private attitude, we are engaging in (b) ________________ behavior.

9. Another theory of attitude change says that we first observe our own behaviors, which in turn causes us to change our attitudes. This is called ________________ theory.

10. If a politician tries to get votes by presenting information with strong arguments, analyses, facts, and logic, he or she is using the (a) ________________ route of persuasion. If a politician seeks votes by emphasizing emotional appeals, focusing on personal accomplishments, and generating positive feelings, he or she is using the (b) ________________ route of persuasion.

11. Persuasion involves at least three elements: We are likely to believe a (a) ________________ who appears honest and trustworthy; if we disagree with the message, it is better if the persuader presents a (b) ________________ message; if the (c) ________________ is less interested in issues, the peripheral route is more effective.

12. Any behavior we perform because of social influences or group pressure, even if that pressure involves no direct requests, is called (a) ________________. A kind of conformity in which we give in to social pressure in our public responses but do not change our private beliefs is called (b) ________________. Any behavior performed in response to an order given by someone in a position of authority is called (c) ________________.



13. An increase in performance in the presence of a crowd is called social (a) ________________; a decrease in performance in the presence of a crowd is called social (b) ________________. An increased tendency for individuals to behave irrationally or perform antisocial behaviors if there is less chance of being personally identified is called (c) ________________. Being socially inhibited to take some action, such as helping, because of the presence of others is called the (d) ________________ effect.

14. A collection of two or more people who interact and share some common attribute or attributes is called a (a) ________________. Togetherness, which is determined by how much group members perceive that they share common attributes, is called group (b) ________________.

15. The phenomenon by which group discussion reinforces the majority's point of view and shifts that view to a more extreme position is called group (a) ________________. If a group makes bad decisions because it is more concerned about reaching an agreement and sticking together than gathering the relevant information and considering all the alternatives, it is referred to as (b)________________.

Answers: *1. (a) social psychology, (b) cognitive social psychology; 2. person perception; 3. (a) stereotypes, (b) prejudice, (c) discrimination; 4. schemas; 5. (a) attribution, (b) disposition, (c) situation; 6. (a) fundamental attribution, (b) actor-observer, (c) self-serving; 7. attitudes; 8. (a) cognitive dissonance, (b) counterattitudinal; 9. self-perception; 10. (a) central, (b) peripheral; 11. (a) source, (b) two-sided, (c) audience; 12. (a) conformity, (b) compliance, (c) obedience; 13. (a) facilitation, (b) inhibition, (c) deindividuation, (d) bystander; 14. (a) group, (b) cohesion; 15. (a) polarization, (b) groupthink*

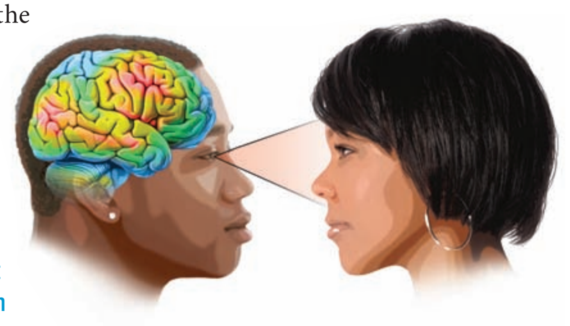
G. Social Neuroscience

Definition

What happens in our brains as we perceive others?

As we learned earlier in this module (p. 582), the area of the brain associated with emotional vigilance becomes activated when White people view unfamiliar Black faces, and the brain area associated with reward and pleasure becomes activated when heterosexual men view faces of attractive women. These research findings are examples of a new interdisciplinary field called social neuroscience.



Social neuroscience examines our brain processes as we perceive others.

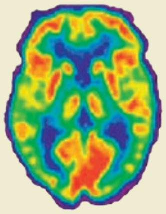
Social neuroscience refers to an emerging area of research that examines social behavior, such as perceiving others, by combining biological and social approaches. In other words, it focuses on understanding how social behavior influences the brain as well as on how the brain influences social behavior (Cacioppo & Berntson, 2002).

Research in social neuroscience has grown dramatically in recent years (Cacioppo et al., 2007). We'll discuss the methods researchers use to study social neuroscience and some of the research findings that have emerged from this recent approach to understanding social behavior.

Methods

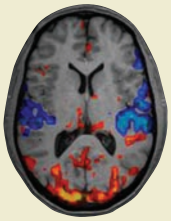
How do we study brain processes?

A variety of techniques are used in social neuroscience to examine the interaction of brain and social processes. As we learned earlier (pp. 70–71), there are several techniques for studying the brain. The common techniques used in social neuroscience to examine brain activity include positron emission tomography (PET scan), functional magnetic resonance imaging (fMRI), electroencephalography (EEG), and transcranial magnetic stimulation (TMS).



PET scan involves injecting a slightly radioactive solution into the blood and then measuring how much radiation is absorbed by neurons. Different levels of absorption are represented by colors—red and yellow indicate maximum activity of neurons, while blue and green indicate minimal activity.

EEG involves placing electrodes at various points across the scalp. The electrodes detect electrical activity (brain wave activity) throughout the brain's surface.



fMRI measures the changes in the activity of specific neurons that are functioning during cognitive tasks, such as thinking about another person.

TMS is a noninvasive technique that sends pulses of magnetic energy into the brain. It works to either activate or suppress brain activity.

Findings

How do we empathize with others?

Perhaps the most fascinating research in social neuroscience has been identifying **mirror neurons,** which are brain cells that are responsible for human empathy. Mirror neurons allow us to put ourselves in other people's shoes and experience how they feel. They are the reason we smile when we see a baby smile or flinch when we see a person in pain. Mirror neurons also explain why yawning is contagious. When we see another person yawn (photo at left), mirror neurons tell our brains to do the same. In fact, I (H. K.) couldn't stop myself from yawning when I looked at this photo! On a more upbeat note, group laughter spreads in much the same way (Dobbs, 2006b). For instance, I always laugh more while watching a comedy in a crowded theater than when I watch one alone at home. Thanks to mirror neurons, I know there is a biological explanation for why these movie watching experiences are so different.

Does this photograph make you yawn?

One of the major areas of social neuroscience research has been racial bias.

Racial bias. Many people who adamantly report being race-blind may unknowingly hold unconscious racial biases, which can come out in unexpected ways. For instance, when White Americans see photos flashed so quickly that they have no conscious awareness of having seen them, the area of the brain that signals "Watch out!" is more active immediately following Black faces than White faces (Begley, 2008a). Another example is the unfortunate case of a White woman married to a Black man who, in a state of rage, unintentionally called her husband a racial slur, only to later feel tremendous shame. In this case, the emotional, more instinctual area of her brain overpowered the rational, more thoughtful area of her brain (Restak, 2006).

Next, we'll discuss a potentially very disruptive social behavior—aggression.

Genes and Environment

Is aggression in a person's genes?

Drive-by shootings, gang fights and killings, spouse and child abuse, school shootings, hate crimes, revenge-shooting by angry workers, bullying, road rage, and extreme forms of hazing are all examples of aggression.

Aggression is any behavior directed toward another that is intended to cause harm.

Animal aggression is largely regulated by genetic factors.

There is no single reason someone turns into a child bully or an aggressive adult but rather three major components: genetic and environmental influences, social cognitive and personality traits, and situational cues (R. A. Baron & Richardson, 2004; B. Bower, 2006a; Kalat & Shiota, 2007). We'll begin with genetic or hereditary influences.

Genetic influences in animals. You can clearly see that genetic influences can regulate aggression by watching the behavior of animals. Ethologists, who study animal behavior in natural settings, have identified numerous social signals that animals have evolved to regulate aggression. For example, the photo below shows a dominant wolf standing above a submissive wolf. The submissive wolf avoids being attacked by lying down and rolling over to expose its vulnerable belly. Many of the dominant and submissive gestures observed in animals are largely programmed by genetic factors and help animals avoid potentially damaging aggressive attacks and improve their chances of survival. Compared with animals, reasons for aggressive acts in humans are much more complicated.

Animals use built-in social signals to threaten or to avoid aggression.

Genetic influences in humans. We all begin life with a different set of genes (pp. 68, 378) that contain chemical instructions that regulate the manufacture and assembly of the many thousands of parts that make up our body and brain. In earlier modules, we discussed how genetic factors contribute 30–70% to the development of many human behaviors, such as personality traits, temperament, intelligence, emotions, motivation, and various mental health problems (Hamer, 2002). Similarly, genetic factors also play an important role in the development of human aggression.

Researchers studied levels of aggression in twins and adopted children to gauge how much genetic factors influence human aggression. If genetic factors influence aggression in humans, then identical twins, who share almost 100% of their genes, should be more alike in committing aggressive behaviors than fraternal twins, who share only 50% of their genes. Also, if genetic factors influence human aggression, then children from aggressive biological parents should be more aggressive, even if adopted by nonaggressive parents. Researchers analyzed over 50 twin and adoption studies and found that genetic factors accounted for about 34% of the total factors that were responsible for developing aggressive and antisocial behaviors (Rhee & Waldman, 2002). These studies show that genetic influences may partly predispose a person to develop aggressive behaviors, but whether this actually occurs depends on the interaction with potentially powerful good or bad environmental influences.

Human aggression is regulated by the interaction of three major components.

Genes interact with good/bad environments. The evidence for the interaction of genetic and environmental factors in aggressive behavior is abundant. Researchers found that a specific gene variation influences brain development to make someone more prone to engage in impulsive violence, but only when the gene variation is combined with environmental stress. Other researchers reported that this same gene variation results in neurotransmitter imbalances, unusually small brain structures associated with emotions, and minimal activity in the prefrontal lobe, which result in poor impulse control and problems regulating emotions (Meyer-Lindenberg, 2006; Mullin & Hinshaw, 2007).

Researchers have also studied the interaction of genetic and environmental factors by following boys who had inherited potentially "bad genes" from their criminally inclined biological parents. Some of these boys were adopted by noncriminal parents and raised in good environments, while others were raised in "bad environments" by criminally inclined adoptive parents. Results showed the combination of "bad genes" interacting with "bad environments" resulted in a large percentage of boys going on to commit criminal acts. However, results also showed that good environments can, to a large extent, compensate for inheriting "bad genes" and can override the development of aggressive or antisocial behaviors (A. Raine, 2002).

Genes interact with child abuse. A tragic and unexplained question is why some children who suffer physical, sexual, or emotional abuse go on to become violent adults, while others do not. Researchers studied a group of severely abused boys who were also found to have a gene that creates abnormal levels of neurotransmitters in the brain. Boys who had the combination of being abused and having this particular gene were twice as likely to have been diagnosed with conduct disorder as a child and three times more likely to have been convicted of a violent crime by age 26. However, if boys who had this particular gene were not abused as children, they weren't any more likely to be antisocial or violent. Researchers concluded that this particular gene did not lead to developing antisocial behaviors unless an individual had also experienced a particular environmental influence—being abused as a child.

Piece of Genetic Code

Genes regulate chemicals in the brain.

The above studies show how genes and environmental factors combine, interact, and influence each other to increase or decrease antisocial or aggressive behaviors (B. Bower, 2006a; Strueber et al., 2006).

Next, we'll examine specific environmental factors and situations that are involved in aggression.

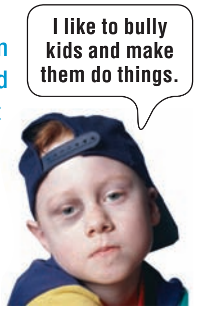
Module 4
A. Genes & Evolution

Social Cognitive and Personality Factors

We have discussed how genetic factors may predispose a person to be aggressive, but whether this occurs depends upon the interaction with environmental factors, such as one's learning experiences. One theory that explains how people learn to be aggressive is Bandura's (2001a) social cognitive theory.



I like to bully kids and make them do things.

Social cognitive theory **says that much of human behavior, including aggressive behavior, may be learned through watching, imitating, and modeling and does not require the observer to perform any observable behavior or receive any observable reward.**

Support for social cognitive theory comes from laboratory and naturalistic studies. A classic laboratory study by Bandura (1965) found that children who observed a model's aggressive behaviors performed similar aggressive behaviors (p. 224). Children who were exposed to aggressive models, such as seeing parents use physical punishment, were reported to show increased aggression with their peers, parents, and dating partners (C. A. Anderson & Huesmann, 2003). These studies show that individuals predisposed to be aggressive are more likely to become so after observing aggressive models in their families, on television, or in video games.

Television/video games. Children have ample opportunity to see, model, and imitate aggressive adults, since the majority of programs on cable and network television contain aggressive actions. By age 18, American youth have seen 200,000 acts of violence on TV, including 40,000 murders (Herr, 2001). When the TV-viewing habits of 700 adolescents were followed into adulthood, researchers found that adolescents who had watched 2 to 3 hours of daily television (all kinds of programs) were almost 4 times more likely to commit violent and aggressive acts later in life compared to those who had watched less than 1 hour a day. Researchers ruled out neglect, poverty, and bad neighborhoods and concluded that frequent TV viewing correlated with committing violent acts later in life (J. G. Johnson et al., 2002). However, it's also possible that aggressive-prone adolescents prefer to watch TV rather than engage in other activities.

TV watching was linked to later aggressive acts.

Model of aggression. One model of how children develop aggressive behaviors points to an interaction among ***genetic/environmental factors,*** which can predispose individuals to develop an irritable or angry temperament and become more or less aggressive depending upon the environment; ***social cognitive factors,*** which involve imitating and modeling the aggressive behaviors observed on television and in video games; and ***personality factors,*** such as being impulsive, having little empathy, and wanting to dominate others. According to this model, the interaction of these three factors increases the chances of a child developing into an aggressive adolescent and an aggressive adult (C. A. Anderson & Bushman, 2002; Tisak et al., 2006).

There are also situational factors that can increase or trigger aggressive behaviors.

Situational Cues

A number of situational cues have been linked to increased aggression, including hot weather (above 90°F), the presence of or easy access to guns, and exposure to violent TV shows and video games (C. A. Anderson & Bushman, 2002). In recent years, another situational cue made the news when more and more drivers became so frustrated and angry by other drivers' annoying driving habits that they responded by aggressively pursuing, ramming, fighting, and even shooting another driver (Galovski et al., 2006). The press labeled this aggressive action by frustrated drivers *road rage,* which shows how frustration can trigger aggression.

The *frustration-aggression hypothesis* says that when our goals are blocked, we become frustrated and respond with anger and aggression.

However, researchers soon discovered that although frustration may lead to aggression, the link between the two is not absolute. Leonard Berkowitz (1989) reviewed the research on the frustration-aggression hypothesis and concluded the following:

- Frustration doesn't always lead to aggression.
- Social rules may inhibit aggression.
- Frustration may result in behaviors other than aggression.
- Cognitive factors can override aggression.

Thus, Berkowitz (1993) modified the original hypothesis.

The *modified frustration-aggression hypothesis* says that although frustration may lead to aggression, a number of situational and cognitive factors may override the aggressive response.

Although our daily lives are often filled with frustrations, we usually find ways to control our frustrations and don't express them in anger, violence, or road rage. However, a child is more likely to react to frustration with violence if he or she has observed and imitated the aggressive behaviors of adults (Osofsky, 1995). Similarly, adults with a personality trait to be impulsive or a genetic tendency to be aggressive are more likely to react to frustration with aggression (Lindsay & Anderson, 2000).

A citizen slyly shows her frustrated feelings toward police.

Summary. We have discussed a number of recent studies on aggression that show how genetic influences interact with environmental factors and how neurotransmitters' levels in the brain affect aggressive behavior (B. Bower, 2006a; R. Raine, 2002). Earlier, we also discussed how the decision-making area of the brain (prefrontal cortex—p. 411) doesn't develop until early adulthood, which explains why adolescents are likely to engage in impulsive and dangerous actions. All these studies point to the importance of biological influences and emphasize that any explanation of human aggression must consider the interaction among three major factors—genes and environment, social cognitive learning and personality traits, and situational cues.

One terrifying and degrading form of aggression is sexual aggression, which we'll examine next.

Sexual Harassment and Aggression

Why do men rape?

According to a National Crime Victimization Survey of U.S. citizens aged 12 and older, there were 191,670 reported rapes and sexual assaults in 2005 (Catalano, 2006). Because only about one-third of rape victims report their attacks to the police, the total number of sexual assaults may be closer to 600,000 annually (AAUW, 2007a). About 51% of rape victims were under 18 years old, and of those, 85% were raped by either a relative or an acquaintance.

National surveys of female college students report that about 20–27% of college women experience either rape or attempted rape, and about 42% experience forced sexual encounters, some of which lead to nonconsensual sexual intercourse (AAUW, 2007a; Flores, 1999).

Most researchers agree that the primary motivation for rape is not sexual but rather a combination of aggression, power, and control (Polaschek et al., 1997). For example, in interviews with ten convicted rapists, nine said that sex was of secondary importance and that either anger or the need to dominate was the most important factor to them (S. Levine & Koenig, 1980).

In the United States, a woman is raped about every 3 minutes.

Another form of aggression is sexual harassment. Researchers found that sexual harassment is widespread and was reported by 40–70% of women and 10–20% of men in occupational settings and by 62% of female and 61% of male college students. Although sexual harassment produces psychological and physical effects in most of the victims, less than 10% of victims file formal complaints (AAUW, 2007a, 2007b; ACA Group, 2004).

Here, we'll focus on rape and sexual assault and begin by describing the common types of rapists.

Characteristics and Kinds of Rapists

Psychologists have identified several developmental factors that are associated with men who rape: They often come from broken homes, did not have a loving caregiver, were sexually or physically abused, were neglected, and spent time in penal institutions (Polaschek et al., 1997). However, these factors alone do not produce rapists; other men who have suffered similar development problems do not become rapists. At present, there is no generally accepted theory of what turns men into rapists.

Researchers have interviewed rapists to understand the motivation behind their sexual aggression. Rapists reported different degrees and combinations of anger, sexual violence, power, and control. Here are descriptions of four types of rapists (Knight, 1992).

The most common rapist is a man who wants to possess his victim.

- The **power rapist,** who commits 70% of all rapes, is not out to hurt physically but to possess. His acts are premeditated and are often preceded by rape fantasies. He may carry a weapon, not to hurt but to intimidate the victim.
- The **sadistic rapist** accounts for fewer than 5% of rapes, but he is the most dangerous because for him sexuality and aggression have become fused, and using physical force is arousing and exciting.
- For the **anger rapist,** rape is an impulsive, savage attack of uncontrolled physical violence. The act is of short duration, accompanied by abusive language, and the victim usually suffers extensive physical trauma, such as broken bones and bruises.
- The **acquaintance** or **date rapist** knows his victim and uses varying amounts of verbal or physical coercion to force his partner to engage in sexual activities.

These examples indicate that men rape for a number of or a combination of reasons, such as to exercise power and control, express anger, and become sexually aroused.

Other factors that contribute to rape are the false beliefs, called rape myths, that some men hold about women.

Rape Myths

One consistent finding about rapists is that they hold negative and demeaning attitudes toward women. For example, here are some of their negative beliefs:

- Healthy women cannot be raped against their will.
- Women often falsely accuse men of rape.
- Rape is primarily a sex crime committed by sex-crazed maniacs.
- Only bad girls get raped.
- If a girl engages in petting and lets things get out of hand, it is her own fault if her partner forces sex on her.

These kinds of statements are called rape myths (Buddie & Miller, 2002; Greensite, 2007).

Rape myths **are misinformed, false beliefs about women, and these myths are frequently held by rapists.**

Some men mistakenly believe that only bad women get raped.

Men who believe in rape myths tend to have a more traditional view of sex roles and hold more negative attitudes toward women. Although researchers found that acceptance of rape myths is more common among men who have raped, rape myths are also held by men in general. For example, one survey of male college students reported that from 17% to 75% of students agreed with one or more of nine rape myths (Giacopassi & Dull, 1986). This association between rape myths and rapists illustrates how negative beliefs and attitudes can contribute to sexual aggression (DeGue & DiLillo, 2005).

In the United States, it is estimated that during their lifetime 20–30% of women will be victims of some type of sexual aggression. Researchers are developing rape prevention programs to both prevent rape and stop the perpetuation of rape myths, and these programs are becoming increasingly common on college campuses (DeGue & DiLillo, 2005; Schewe, 2002). We'll discuss ways to prevent sexual aggression in the Application section.

Next, we'll examine programs psychologists have developed to change attitudes toward aggression.

I. Application: Controlling Aggression

Case Study

Why did only one of six children develop into a violent adult?

In a family of six children, one was so bad he was nicknamed Monster Kody. He became a gang member and shot his first victim at age 11. Kody continued his violent and aggressive ways until he was arrested, convicted, and sentenced to jail for robbery. When he wrote his autobiography from his prison cell, he blamed his problems and violent behavior on his parents' poverty and destitution and on his belonging to a violent gang. But as it turned out, Monster Kody had three brothers and two sisters who grew up in the same poverty and destitution but developed into law-abiding citizens who are leading very productive lives (Azar & Sleek, 1994).

Out of six children raised in the same environment, only one, Monster Kody, became an aggressive adult. This shows that the development of aggressive behavior depends on the interaction of the three factors that we have discussed: genetic and environmental, social cognitive, and personality factors. Because genetic and environmental factors are sometimes difficult to change, recent programs focus on social cognitive factors to reduce and control aggression.

Controlling Aggression in Children

Most children have occasional outbursts of anger and aggression, but if these outbursts become frequent, young children may develop a pattern of using aggressive behaviors to deal with problems (Lemerise & Dodge, 2000). Researchers found that, unless treated, an aggressive child will surely become an aggressive adolescent and adult and develop later problems, such as substance abuse, criminality, and mental health disorders (Broidy et al., 2003). Researchers have discovered that aggressive children have a number of cognitive-behavioral deficits that make them perceive, remember, and react to a world that appears more hostile than it really is. We'll first discuss these cognitive-behavioral deficits and then a treatment program.

Aggressive children usually become aggressive adolescents and adults.

Cognitive-Behavioral Deficits

Parents and teachers need to realize that an aggressive child or teenager does not perceive the world, take feedback, or act as regular nonaggressive children do. Here are some of the ways that aggressive children differ (Lochman et al., 2006; Spielman & Staub, 2000):

- An aggressive child **does not accurately perceive or recall social cues.** For example, the aggressive child selectively attends to aggressive or hostile actions and overlooks positive social cues. When an aggressive child is asked to recall what happened that day, the child tends to remember all the hostile actions rather than any friendly cues.

You know I've got a quick temper, so don't make me angry!

- An aggressive child **does not make accurate explanations** or attributions of the situation. For instance, aggressive children tend to attribute hostile actions to other children when, in fact, other children are not behaving in an aggressive or hostile way.
- An aggressive child **does not have many adaptive solutions** to problems. This means aggressive children tend to use hostile and aggressive actions to solve many of their problems rather than using nonhostile or verbal solutions.
- An aggressive child **is reinforced for aggressive behaviors** rather than for positive social behaviors. That's because aggressive children get their way by using hostile actions, which in turn are reinforced. Aggressive children **have poor social skills,** which means they rarely solve problems in nonaggressive ways, such as by discussion.

Because of these cognitive-behavioral deficits, aggressive children perceive a more hostile world and respond with more aggressive behaviors (Lochman et al., 2006). There are programs that teach children how to control their aggression.

Programs to Control Aggression

Children who engage in antisocial and aggressive behaviors are usually described by the term *conduct disorder,* which is one of the most frequent reasons for referral to treatment programs (Ollendick et al., 2006). We'll discuss two successful programs for treating conduct disorder.

Cognitive problem-solving skills training. A well-researched treatment program involves helping aggressive children overcome the deficits in cognitive-behavioral skills that we just discussed. For example, because an aggressive child does not know how to stop thinking and acting in aggressive ways, therapists teach the child specific rules, such as no matter how angry the child gets, he or she must not hit, yell, or kick. The child receives special reinforcement for obeying these rules. The child learns to use self-statements to inhibit impulsive behavior, including "I can stop myself." The child learns to use alternative, nonaggressive solutions when frustrated. These might be hand clapping, scribbling on a sheet of paper, or tensing and relaxing muscles. Cognitive programs have reduced the aggression of children in both home and school (Nangle et al., 2002; C. R. Thomas, 2006).

Parent Management Training (PMT). An effective treatment program for conduct disorder is called Parent Management Training, or PMT (Mash & Wolfe, 2007). In this program, a therapist teaches parents how to use specific procedures in the home to alter angry interactions with their child, to decrease deviant behaviors, and, very important, to promote positive or prosocial behaviors. For example, parents learn to not reinforce aggressive behaviors that a child uses to get his or her way, to establish and enforce reasonable rules, and to reinforce appropriate behaviors. PMT has proven very effective in decreasing aggressive behaviors in the home and school (C. R. Thomas, 2006).

Now, we'll examine methods of controlling aggression in adults.

Controlling Anger in Adults

How do I stop being angry?

You've probably known people who get mad, rant and rave, and then take their anger out on whoever happens to be near. Then, after their violent outbursts, they may apologize, say they're sorry, or explain that they have to let out their angry feelings or they'll explode. Is it true that "letting it all out" is a good way to deal with anger?

Catharsis

A popular idea for reducing and controlling aggression involves catharsis.

Catharsis **is a psychological process through which anger or aggressive energy is released by expressing or letting out powerful negative emotions.**

According to the concept of catharsis, a good way to deal with anger or aggression is to "let off steam," which means expressing strong negative emotions by yelling, arguing, hitting, or kicking something.

Sigmund Freud used the term *catharsis* to mean that one should let frustration and anger out so that they don't build up and explode in an aggressive rage. However, most research does not support Freud's conclusion about the usefulness of catharsis. For example, after college students were made angry, some were told to punch a bag while thinking about the person who made them angry (catharsis group), while others were told only to sit quietly for 2 minutes (control group). Afterward, students in the catharsis group, who vented their anger, rated their anger higher than those in the control group, who did nothing to let it out. The researcher concluded that venting to let anger out (catharsis group) was like pouring gasoline on a fire; it only adds fuel and makes the anger worse. Accordingly, it's bad to vent one's anger by punching a pillow, since it seems to only make the anger worse (Bushman, 2002). A better way to deal with anger, at the job, school, home, or on the road, is to use a cognitive-relaxation program.

I'll get you for cutting me off, you dumb . . . !

Cognitive-Relaxation Program

At the urging of his wife, Rob came to therapy because he's prone to angry outbursts, especially when driving. He says things like, "I'm not doing anything unsafe; it's that jerk in front of me who's going too slow." Rob admits to getting angry at one thing or another many times a day (Holloway, 2003). Rob can learn to gain control over his anger with an anger management program.

One such successful program is the cognitive-relaxation program. It begins by having Rob observe and later write down his behaviors (feeling tense) and anger-producing thoughts ("That guy's a jerk") during several days of driving. This process is called self-monitoring and helps Rob make a record of the anger-producing thoughts and behaviors that he may not have been aware of and that trigger and maintain his anger. Next, Rob learns a method to quickly relax himself on cue (progressive relaxation—p. 503) so that he will be able to reduce his body tension and arousal. He also makes a list of positive thoughts ("That guy's a careful driver," "That guy is trying to avoid an accident") that he can substitute for his anger-producing ones ("That driver's a jerk"). Once Rob has learned to relax on cue and has his list of positive thoughts, he's ready to begin driving while substituting positive for negative thoughts and relaxing on cue whenever he begins to feel tense or angry. Being able to relax on cue is important because it's very hard to get angry if you're relaxed. Researchers found that this cognitive-relaxation program has proved very effective in helping individuals reduce and control their anger (Deffenbacher, 2003, 2005).

Controlling Sexual Coercion

What are the risks?

Several studies have found that from 42% to 78% of college women report sexual coercion, which includes men using social pressure, verbal coercion, lies, alcohol or drugs, emotional manipulation, or threat of force to have sexual contact with women (Struckman-Johnson et al., 2003). Part of the socialization of males involves seeing situations that may reinforce and increase their risk of using sexual coercion. For example, the media (movies, videos, songs) portray situations in which men believe that using sexual coercion does no harm and may even be arousing to their partners, or may be necessary to achieve their goals (Lonsway & Fitzgerald, 1994). These media portrayals reinforce the idea that sexual coercion is acceptable and even arousing to women and increase the risk that men will be sexually coercive and not be perceptive and responsive to a woman's wishes or refusals.

Somehow the socialization creates a difference between men who are sexually coercive and those who are not. For example, men who report higher levels of sexual coercion also perceived women as showing higher levels of sexual interest in nonsexual, mundane situations (having a conversation). Researchers concluded that, in these cases, it is not the women's behaviors that put them at risk for sexual coercion but rather it is that sexually coercive men misperceive women as showing sexual interest when they are not (Bondurant & Donat, 1999). These researchers suggest that prevention programs need to educate sexually coercive men about how they may misperceive the sexual interest of women, even in very mundane situations like ordinary conversations.

According to researchers, one way to avoid sexual coercion on a date is for men and women to know the risk factors. For women, these include the heavy use of alcohol or other drugs that dull reason and perception. For men, these include overuse of drugs, thinking that paying the expenses entitles him to sex, misperceiving his date's sexual interest, and not recognizing that "NO" means "NO!" (Struckman-Johnson et al., 2003).

One problem is that some males do not take "NO!" for an answer.

Summary Test

A. Perceiving Others

1. How our thoughts, feelings, perceptions, and behaviors are influenced by interactions with others is studied in the field of (a) ________ psychology. A branch of this field studies how people perceive, retrieve, and interpret information about social interactions; this branch is called social (b) ________.

2. Making judgments about the traits of others through social interactions and gaining knowledge from our social perceptions are part of person (a) ________. This process is aided by a wealth of social information that is stored in our memories. However, some memories can bias our perceptions. Widely held beliefs that people have certain traits because they belong to a particular group are called (b) ________. Negative beliefs that are often accompanied by an unfair, biased, or intolerant attitude toward another group of people are called (c) ________. Specific unfair behaviors exhibited toward members of a group are called (d) ________.

3. Cognitive structures that represent an organized collection of knowledge about people, events, and concepts are called ________. They help us select and interpret relevant information from a tremendous amount of incoming social information and provide guidelines for how we should behave in different situations.

4. There are different kinds of schemas: Those that include our judgments about the traits that we and others possess are called (a) ________ schemas; those that are based on the jobs people perform or the social positions they hold are called (b) ________ schemas; those that contain behaviors that we associate with familiar activities, events, or procedures are called (c) ________ schemas, or scripts.

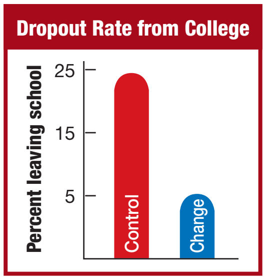
B. Attributions

5. The factors or events that we point to as causes or explanations for people's behavior are called (a) ________. If we attribute behavior to the internal characteristics of the person performing the behavior, we are using (b) ________ explanations; if we attribute behavior to the circumstances or context of that behavior, we are using (c) ________ explanations.

6. Harold Kelley proposed that in deciding between dispositional and situational explanations, we should look for factors that change along with the behavior we are trying to explain; this is called the ________ model. To decide between dispositional and situational explanations, we should look for consensus, consistency, and distinctiveness.

7. An error that we make by attributing the cause of a behavior to a person's disposition and overlooking the demands of the environment or situation is the (a) ________ attribution error. If we attribute our own behavior to situational factors but others' behaviors to their dispositions, we fall prey to the (b) ________ effect. If we attribute success to our disposition and failure to the situation, we use the (c) ________ bias.

C. Research Focus: Attributions & Grades



8. Researchers found that freshmen who were encouraged to attribute their academic problems to ________ conditions, such as poor study habits, showed a significant improvement in grade point average and were less likely to drop out than were students who continued to attribute their poor performance to permanent factors.

D. Attitudes

9. Beliefs or opinions that include a positive or negative evaluation of an object, person, or event and that predispose us to act in a certain way are called (a) ________. General attitudes are convenient guidelines for interpreting and categorizing objects and events and deciding whether to approach or avoid them. Attitudes have three components: beliefs and ideas make up the (b) ________ component; emotions and feelings make up the (c) ________ component; and predispositions make up the (d) ________ component.

10. A state of unpleasant psychological tension that motivates us to reduce our inconsistencies and return to a more consistent state is called (a) ________. To reduce this tension and return to a more consistent state, we may add or change (b) ________ or take a public position that is counter to our private attitude, which is called engaging in (c) ________ behavior. According to Daryl Bem's theory, we first observe or perceive our own behavior and then infer attitudes from that behavior; this is called (d) ________ theory.

11. One method of persuasion presents information with strong arguments, analyses, facts, and logic; this is the (a) ________ route, which works primarily on the cognitive component of our attitudes. Another route emphasizes emotional appeal, focuses on personal traits, and generates positive feelings; this is called the (b) ________ route and works primarily on the affective or feeling component. Three factors to consider in persuasion are the source, (c) ________, and (d) ________.

Figure/Text Credit: (#8) Bar graph data from "Improving the Academic Performance of College Freshman," by T. D. Wilson and P. W. Linville, 1982, *Journal of Personality and Social Psychology, 42,* 367–376, American Psychological Association.

E. Cultural Diversity: National Attitudes & Behaviors

12. National attitudes are important because they predispose citizens to (a) ________ in certain ways. For example, compared to the West, traditional Nigerian attitudes are for a woman to become beautiful by (b) ________ a lot. One reason Egyptian women are having such difficulty changing (c) ________ toward them is that these discriminatory policies are backed by social, political, and religious forces.

F. Social & Group Influences

13. If you perform a behavior because of group pressure, you are exhibiting (a) ________. Giving in to social pressure in your public responses but not changing your private beliefs is called (b) ________. A sales technique that relies on the increased probability of getting a second request if you obtain compliance with a small first request is called the (c) ________ technique. Performing a behavior in response to an order given by someone in authority is called (d) ________.

14. Any behavior that benefits others or has positive social consequences is called (a) ________ behavior. A form of helping that involves doing something, often at a cost, for reasons other than the expectation of a material or social reward is called (b) ________.

15. A collection of two or more people who interact and share some common attribute or attributes is called a (a) ________. How much group members perceive that they share common attributes determines group (b) ________. The formal or informal rules about how group members should behave are called group (c) ________. According to Leon Festinger's (d) ________ theory, we compare ourselves to others who are similar to us so that we can measure the correctness of our attitudes and beliefs.

16. If the presence of a crowd increases performance, it is called social (a) ________; if it decreases performance, it is called social (b) ________. If people in a crowd take on antisocial roles because they cannot be identified easily, it is called (c) ________. If an individual in a crowd is inhibited from helping someone in need, it is called the (d) ________ effect.

17. The effect in which a group discussion reinforces the majority's point of view and shifts that view to a more extreme position is called (a) ________. If a group makes a bad decision because it emphasizes sticking together over gathering data and considering all the alternatives, that is called (b) ________

G. Social Neuroscience

18. Social neuroscience refers to a research area that examines social behavior, such as perceiving others, by combining ________ approaches.

19. Brain cells responsible for human empathy are called ________.

H. Aggression

20. The findings that identical twins are more alike in aggression and that not all abused children become aggressive are evidence for (a) ________ influences on aggression. The finding that people can learn aggressive behavior through observation, imitation, and self-reinforcement supports the influence of (b) ________ factors. The finding that frustration may lead to or trigger aggression supports the influence of (c) ________ factors. Unlike humans, aggression in animals is primarily influenced by (d) ________ factors.

21. The primary motivation for rape is not sexual but a combination of ________, ________, and ________.

I. Application: Controlling Aggression

22. An aggressive child perceives and reacts to a world that appears more hostile than normal because this child has a number of (a) ________ deficits. Children can learn to control their aggressive behavior by being reinforced for obeying certain (b) ________. Freud believed that adults should release frustration by acting out, which reduces anger and is called (c) ________. Freud's idea is not supported by modern research. A successful anger management program for adults is called the (d) ________ program.

Answers: *1. (a) social, (b) cognitive social psychology; 2. (a) perception, (b) stereotypes, (c) prejudice, (d) discrimination; 3. schemas; 4. (a) person, (b) role, (c) event; 5. (a) attributions, (b) internal (dispositional), (c) external (situational); 6. covariation; 7. (a) fundamental, (b) actor-observer, (c) self-serving; 8. temporary; 9. (a) attitudes, (b) cognitive, (c) affective, (d) behavioral; 10. (a) cognitive dissonance, (b) beliefs, (c) counterattitudinal, (d) self-perception; 11. (a) central, (b) peripheral, (c) message, (d) audience; 12. (a) behave, (b) eating, (c) attitudes; 13. (a) conformity, (b) compliance, (c) foot-in-the-door, (d) obedience; 14. (a) prosocial or helping, (b) altruism; 15. (a) group, (b) cohesion, (c) norms, (d) social comparison; 16. (a) facilitation, (b) inhibition, (c) deindividuation, (d) bystander; 17. (a) group polarization, (b) groupthink; 18. biological and social; 19. mirror neurons; 20. (a) genetic and environmental, (b) social cognitive, (c) situational, (d) genetic; 21. power, aggression, control; 22. (a) cognitive-behavioral, (b) rules, (c) catharsis, (d) cognitive-relaxation*

Why the Debate over Teen Vaccination?

What if modern medicine could prevent three-quarters of the occurrences of a leading cause of cancer in women and save almost 300,000 lives each year? A major public health breakthrough makes this possible. The first vaccine to protect women against cervical cancer is now available, but it comes with much controversy.

Cervical cancer is caused by HPV (human papillomavirus), the most common sexually transmitted infection in the United States. Cervical cancer usually strikes when a woman is young, often before she has had children, and the treatment may cause infertility. Because cervical cancer is the leading cause of cancer death in women and its treatment has serious risks, prevention is essential.

A vaccine that prevents infection of four types of HPV and comes with minimal side effects is now available. The vaccine is 100% effective in targeting certain causes of cervical cancer that together make up about three-quarters of all cervical cancer cases. Despite its effectiveness and safety, the use of the vaccine has provoked considerable social controversy.

Because many teens contract HPV within only a few years after their first sexual experience, it is recommended that the vaccine be administered to girls during their early teens. Some conservative officials and parents oppose vaccinating teen girls, stating the vaccine undermines their value of abstinence being the best method to avoid getting HPV. These same opponents fear that vaccinating young teens against a sexually transmitted infection, such as HPV, conveys approval to be sexually promiscuous.

Alan Kaye, the executive director of the National Cervical Cancer Coalition, disagrees with opponents who worry the vaccination will result in girls becoming sexually promiscuous. He responds to these moral objections by comparing the vaccine to wearing a seat belt: "Just because you wear a seat belt doesn't mean you're seeking out an accident" (R. Stein, 2005). Others argue the cervical cancer vaccine is no different from routine vaccines that protect children from diseases such as measles, polio, or chicken pox.

Texas Governor Rick Perry decided the benefits of the vaccine outweighed the moral concerns. Texas became the first state to require girls to be immunized before the 6th grade. Since then about two dozen states considered making similar requirements; however, only Virginia and the District of Columbia have moved toward requiring girls to receive the shot.

Concerns raised about the vaccine that are unrelated to morality include its high cost ($360), uncertainty about how long the vaccine will be effective, and possible side effects. Despite these concerns, more than 25% of teenage girls have already received the HPV vaccine. Advocates are optimistic that up to 90% of teenage girls will eventually receive the HPV vaccine.

In addition to the HPV vaccine targeting the major causes of cervical cancer, it protects against the causes of 90% of all genital warts cases and may reduce the risk of oral cancer. Consequently, another social debate is deciding whether boys should be vaccinated as well. (Adapted from Associated Press, 2005e; Bosch et al., 2002; DeNoon, 2008; FDA, 2006; Gostout, 2007; Hitti, 2006a; M. Kaufman, 2006b; Kotz, 2007c; MSNBC, 2006; L. A. Peterson, 2007; R. QUESTIONS

1 What role does brain development play in adolescents' likelihood of having safe sex to reduce the chances of getting infected with HPV?

2 How do the three components of attitude apply to the conservatives' position?

3 Why has preaching abstinence not been more successful in preventing girls from getting HPV?

4 Which group attitudes or norms do the members of the conservative side share? How does a group benefit by sharing norms?

5 What type of persuasion are advocates of the vaccine mostly using to pass legislation?

6 What needs to happen for a parent opposed to vaccinating a teen to change his or her attitude toward teens getting vaccinated?

Study Guide and WebTutor

Work through the corresponding module in your Study Guide for tips on how to study effectively and for help learning the material covered in the book. WebTutor (an online Study Tool accessed through your eResources account) provides an interactive version of the Study Guide.

Suggested Answers to Critical Thinking

1. The executive functions in the adolescent's brain are not yet fully developed, which helps explain an adolescent's tendency to take risks (p. 411). Adolescents simply do not have the neural bases to carefully analyze risks and make intelligent decisions, such as to always use protection when having sex.
2. **Cognitive component:** believe in abstinence and negatively evaluate vaccinating teen girls. **Affective component:** have strong feelings about abstinence being the best course of action and fear that vaccination may send the wrong message to teens. **Behavioral component:** refuse to allow teens to receive the vaccine.
3. The problem is that changing attitudes and beliefs is difficult, especially in this case, when national surveys report that about 50% of teenagers have sex by age 17. In attempts to change attitudes through persuasion, many factors are involved: whether to use facts and logic, the central route, or use emotional appeals, the peripheral route; whether a one-sided or a two-sided message will be more effective; and who will be the most believable and trusted source of the message: the parents, teachers, minister, peers, or boyfriends.
4. One of the main attitudes or norms conservatives share is that abstinence, especially for teenagers, is the best policy to avoid getting HPV. The group comes together and develops group cohesion by sharing common attitudes or norms.
5. Advocates are using strong arguments, facts, and logic to persuade others to permit teen girls to receive the vaccine, which indicates they are using the central route for persuasion.
6. Parents who oppose vaccinating teens expect their daughter to abstain from sex. But, if their daughter does not abstain from sex and gets cervical cancer, these parents will develop conflicting beliefs (the vaccine is immoral, but it can help save lives) that would cause cognitive dissonance. They might resolve this dissonance by changing their belief or engaging in counterattitudinal behavior.

Descriptive Statistics

Do numbers speak for themselves?

Suppose you are curious about how many people are capable of being hypnotized. You read up on how to induce hypnosis and put together a list of five things that people under hypnosis have been known to do, such as feeling no pain when a finger is pricked, being unable to bend an arm when told that the arm will remain stiff, and acting like a young child when told to regress to infancy.

You next persuade 20 people to participate in a little test. You attempt to hypnotize them and then ask them to do each of the things on your list. Of your 20 subjects, 2 follow none of your suggestions, 4 follow only one, 7 go along with two suggestions, 4 go along with three, 2 go along with as many as four, and only 1 follows all five.

The next day, a friend asks you how your study worked out. How would you make generalizations about your findings?

To answer this type of question, psychologists rely on *statistics*. Although you often hear that numbers "speak for themselves," this is not really true. Numbers must be sorted, organized, and presented in a meaningful fashion before they tell us much.

Statistics are the tools researchers use to analyze and summarize large amounts of data.

If the very word *statistics* brings to mind complex formulas you think you could never master, you may be surprised to realize how much you already use statistics in your everyday life. When you hear that a ball player has a batting average of .250 and you know this means he has gotten one hit in every four times at the plate, you are using statistics. When you understand that a rise in the median income means that people, on average, are earning more money, you are understanding statistics. When you know that scoring in the 90th percentile on a final exam means you did better than nine out of ten of your classmates, you are showing a grasp of statistics—specifically, descriptive statistics.

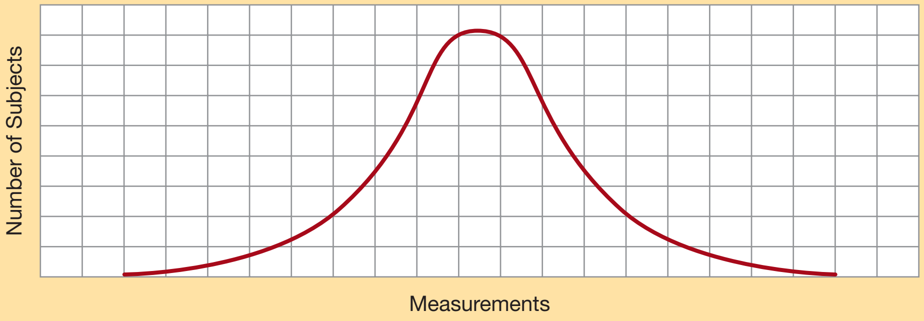
Descriptive statistics are numbers used to present a collection of data in a brief yet meaningful form.

One important part of descriptive statistics is presenting distributions of measurements and scores.

Frequency Distributions

Individual differences show up in everything that can be measured. There are no measurements—whether of height, heart rate, memory capability, shyness, or political opinion—that do not show individual variation.

Figure A.1
A normal curve.



The ***frequency distribution*** is the range of scores we get and the frequency of each one when we measure a sample of people regarding some trait.

Frequency distributions are often presented in graphic form so their patterns can be seen at a glance. We'll discuss two of these distributions, normal and skewed.

What is a normal distribution?

For many traits in a large population, the frequency distribution has a characteristic pattern. For instance, if you measured the height of 500 students chosen at random from your school, you would find a few very short people and a few very tall people, while the height of the majority of students would be somewhere in the middle. Height, like weight, IQ, years of education, and many other characteristics, has what is known as a ***normal distribution.*** When graphed, a normal distribution produces a normal curve.

A ***normal curve*** is a graph of a frequency distribution in which the curve tapers off equally on either side of a central high point.

This characteristic bell shape (Figure A.1) shows that most of the measurements fall near the center, with as many falling to one side as to the other. When you measure a trait that is distributed normally throughout a population, your measurements should produce an approximately normal curve, provided that your sample is large enough.

What is a skewed distribution?

Not all traits are distributed normally.

Skewed distributions are distributions in which more data fall toward one side of the scale than toward the other.

When plotted on a graph, skewed distributions do not have a symmetrical shape. Instead, they have a "tail" on one end, which shows that relatively fewer frequencies occur on that side of the horizontal scale. When the tail is on the right, as in Figure A.2, we say the distribution is skewed to the right, or has a *positive skew* (there are fewer frequencies at the higher end of the horizontal scale). When the tail is on the left, as in Figure A.3, we say the distribution is skewed to the left, or has a *negative skew* (there are fewer frequencies at the lower end of the horizontal scale).

The data you collected about susceptibility to hypnosis present a skewed distribution. If you plotted them on a graph, with score along the horizontal axis and number of people along the vertical one, the curve would be skewed to the right. This would show at a glance that more people in the sample fell at the low end of your hypnotic susceptibility scale than fell at the high end.

In fact, your sample is fairly representative of the general population. About twice as many people are poor hypnotic subjects as are excellent ones. But note that to be assured of obtaining the true distribution in a large population, you would usually have to test quite a large representative sample.

Figure A.2
A curve skewed to the right (a positive skew).

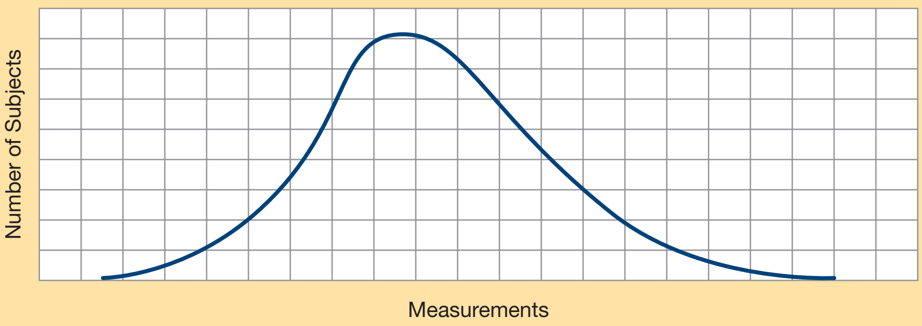


Figure A.3
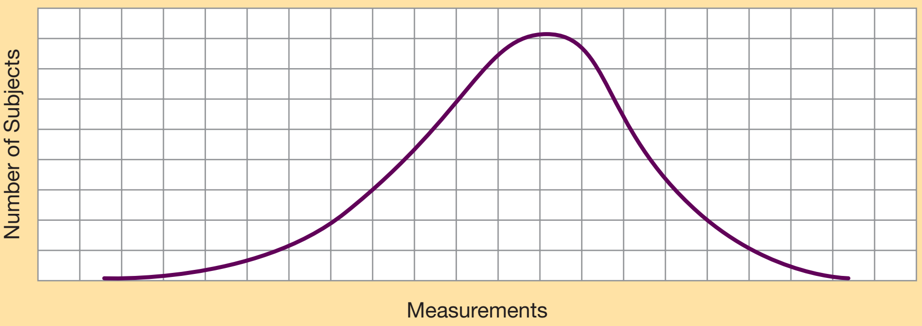
A curve skewed to the left (a negative skew).



Measures of Central Tendency

Suppose you want to summarize in a few words the average height of people, the typical susceptibility to hypnosis, or the most common performance on an IQ test. For this you would need another kind of descriptive statistic, called a ***measure of central tendency.*** There are three measures of central tendency: the mean, the median, and the mode. Each is a slightly different way of describing what is "typical" within a given distribution.

The ***mean*** is the arithmetic average of all the individual measurements in a distribution.

Suppose that ten students in a seminar took an exam. Their scores were 98, 96, 92, 88, 88, 86, 82, 80, 78, and 72. You would find the mean by adding all the scores and dividing the sum by the total number of scores. In this case, the sum of all the scores is 860; dividing this by 10 gives a mean of 86.

The ***median*** is the score above and below which half the scores in the distribution fall.

If you took our ten test results and arranged them in order from highest to lowest, the median would be the point right in the middle, between the fifth and sixth scores on the list. That would be 87.

The ***mode*** is the most frequent measurement in a distribution.

In this group of scores, the mode, the score that occurs most often, is 88.

In the example just given, the mean, median, and mode are very close together, but this is not always true. In some distributions, particularly those that are strongly skewed, these three measures of central tendency may be quite far apart. In such cases, all three of the measures may be needed to give a complete understanding of what is typical.

For instance, look at the graph in Figure A.4, which shows the distribution of income in an imaginary company. The mean income of its 50 employees is $30,600 a year. But look at the distribution. The president of the company earns $140,000, three other executives earn $80,000, and another four earn $60,000 a year. There are also six lower-level managers at $40,000, six salespeople at $30,000, and ten foremen at $25,000. The rest of the employees, the 20 people who keep the company records and run the machines, earn only $12,000 each. Thus, the mean of $30,600 does not really give an accurate indication of a typical income of an employee at this firm.

A better measure of central tendency in this instance is probably the median, or $25,000. It tells us that half the people at the company earn no more than this amount.

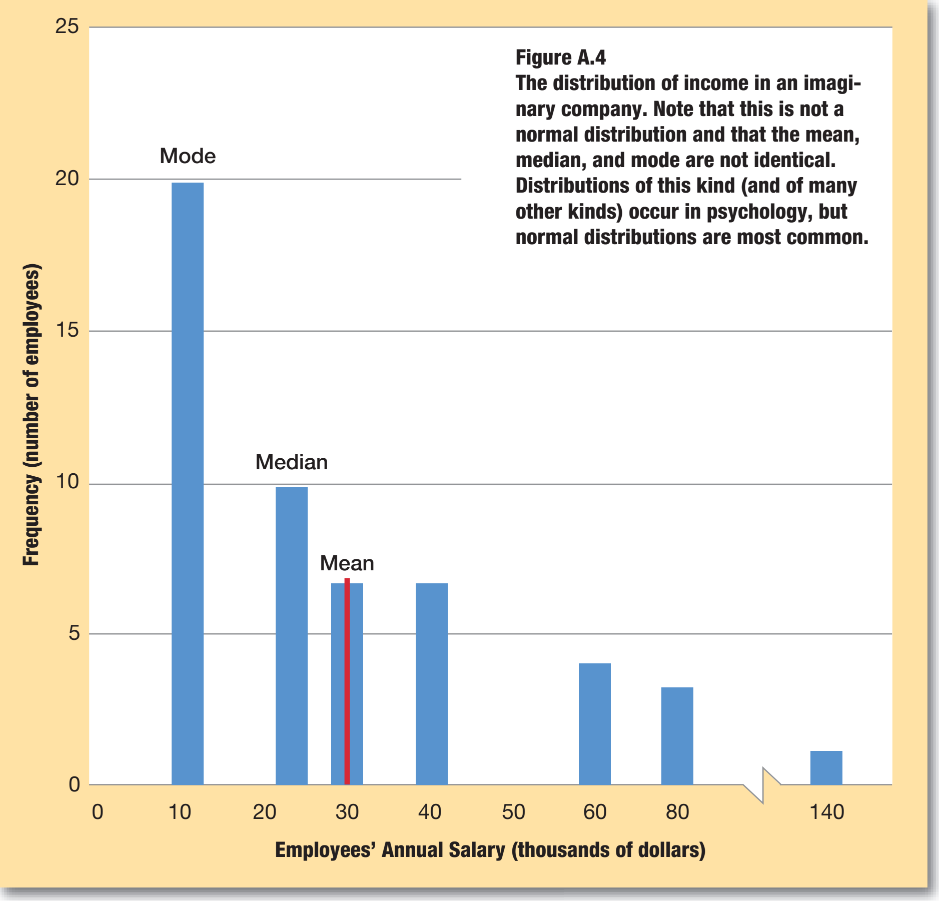


Figure A.4
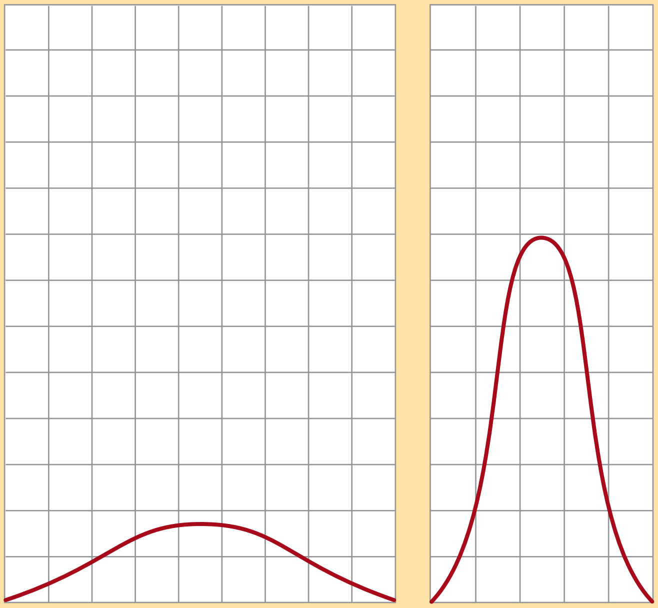
The distribution of income in an imaginary company. Note that this is not a normal distribution and that the mean, median, and mode are not identical. Distributions of this kind (and of many other kinds) occur in psychology, but normal distributions are most common.

Figure A.5
At left, a distribution with a great deal of variability. At right, a distribution with little variability.



Also revealing is the mode, or most common salary; it is only $12,000 a year. As you can see, the mean, median, and mode can provide us with very different figures.

Measures of Variability

If you get an A in a course and are told that the grades ranged from A to F, you will feel a greater sense of accomplishment than if the grades ranged only from A to B. Why this difference in how you perceive a grade? The answer is that it is often important to take into account the extent to which scores in a distribution are spread out. In other words, it is often informative to have a measure of variability.

A ***measure of variability*** is an indication of how much scores vary from one another.

On a graph, scores that vary greatly produce a wide, flat curve; scores that vary little produce a curve that is narrow and steep. Figure A.5 illustrates these two patterns.

One measure of variability is the range.

The ***range*** is the difference or interval between the highest and lowest scores in a distribution.

Another measure is the standard deviation.

The ***standard deviation*** shows how widely all the scores in a distribution are scattered above and below the mean.

If scores cluster closely around the mean, the standard deviation will be small; if scores are dispersed widely from the mean, the standard deviation will be large. Thus, the standard deviation is an indication of how representative the mean is. If the standard deviation is small, we know that the mean is representative of most scores in the distribution. Conversely, if the standard deviation is large, we know that many scores are quite far from the mean.

Figure A.6 shows that the standard deviation divides a normal curve into several portions, each of which has a certain percentage of the total distribution. As you can see, 68.2% of all scores fall somewhere between the mean and one standard deviation to either side of it. If you move two standard deviations to either side of the mean, you will take in 95.4% of all the scores in the distribution. Finally, 99.8% of all the scores will fall between the mean and three standard deviations from it. Only a scant 0.2% fall beyond three standard deviations.

How to Find the Standard Deviation

Finding the standard deviation of a distribution is not difficult, although it is tedious without the aid of a calculator. To compute the standard deviation, follow these five steps:

1. Determine the mean of all the measurements in the distribution.
2. Subtract the mean from each measurement and square the difference. (Squaring the difference eliminates the negative signs that result when dealing with measurements that fall below the mean.)
3. Add the squares together.
4. Divide the sum of the squares by the number of measurements.
5. Take the square root of the value you obtained in step 4. This figure is the standard deviation.

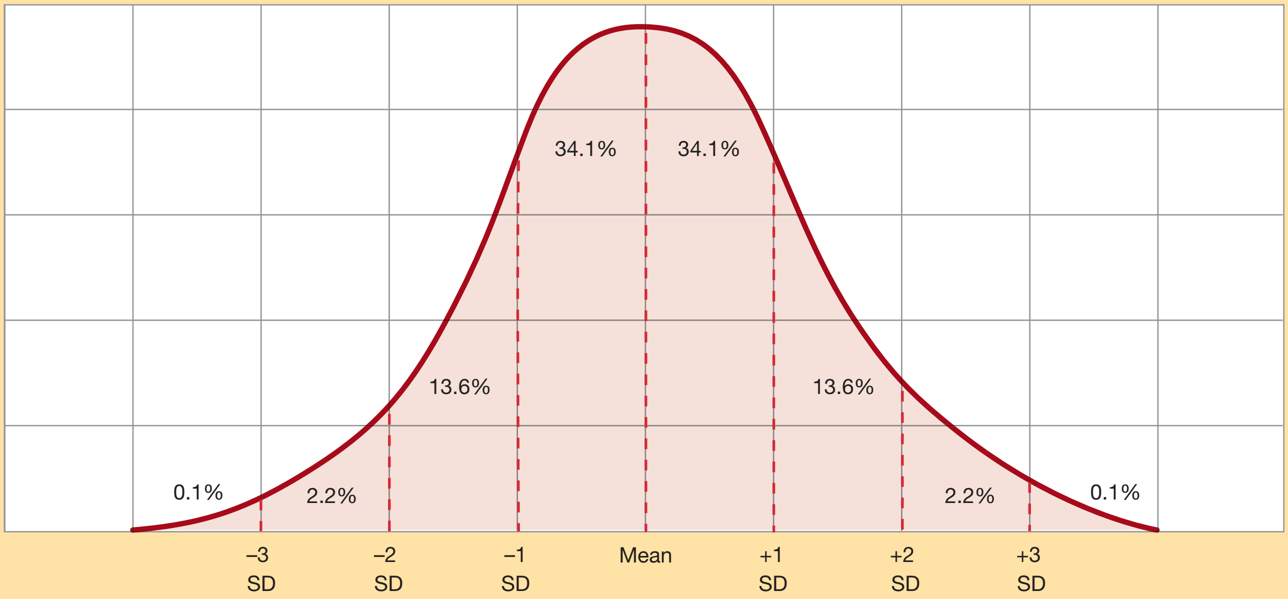
Knowing the mean and the standard deviation of any normal distribution allows you to determine just how "average" any given score is. For instance, suppose you take a difficult test consisting of 100 questions and receive a score of 80. How well did you perform? If you learn that the mean is 60 and the standard deviation is 8, you know that your score of 80 is very good indeed. The overwhelming majority of people—95.4%—scored no better than 76, or two standard deviations above the mean. Thus, relative to what most others have done, an 80 is excellent. By the same token, a 40 is not very good at all; 95.4% of people scored 44 or higher on this test. Thus, if you received a 40 you are near the bottom of the distribution and had better start studying much harder.

Inferential Statistics

Can scientists be 100% certain?

In the mid-1970s, many Americans were puzzled to learn that a distinguished panel of scientists could not determine with absolute certainty whether the artificial sweetener called cyclamate posed a risk of cancer. The scientists announced that, after months of research, costing millions of dollars, they could be only 95% sure that cyclamate was safe. Why this remaining margin of doubt? Why can't a team of highly skilled researchers, backed by government funds, manage to tell us absolutely if a substance is hazardous to our health?

Figure A.6
A normal distribution showing the percentage of measurements that fall within one, two, or three standard deviations from the mean.



Chance and Reliability

No one can totally eliminate the influence of chance on scientific findings. Even when you randomly select groups of subjects, there is always the possibility that, just by chance, those groups will differ slightly in ways that affect your experiment. This is why scientists must rely on statistics to tell them the likelihood that a certain set of results could have happened purely by chance. If this likelihood is small—5% or less—the researchers are justified in rejecting the chance explanation and in concluding instead that their findings are probably reliable. *Reliable* means that the investigators would probably obtain similar results if they repeated their study over and over with different groups of subjects.

Determining the reliability of experimental findings is a major way in which psychologists use inferential statistics.

Inferential statistics **are a set of procedures for determining what conclusions can be legitimately inferred from a set of data.**

These procedures include what are called ***tests of statistical significance.*** Tests of statistical significance were used to determine the 95% certainty of the finding that cyclamate is safe to eat. Different tests of statistical significance are needed for different kinds of data.

Tests of Statistical Significance

Suppose you are an educational psychologist who has put together a special program to raise the IQ levels of children with learning disabilities. You expose one group of children with learning deficits to the special program and another group, with equal learning deficits, to the standard curriculum. At the end of a year, you give all the subjects an IQ test. Those in the special program score an average of ten points higher than those in the standard curriculum. Is this enough of a difference to reject the chance explanation and conclude that the program was a success? The procedure most frequently used to answer questions like this is a test of statistical significance called the *t* test.

What is a *t* test?

The *t test* is an estimate of reliability that takes into account both the size of the mean difference and the variability in distributions. The *greater* the mean difference and the *less* the variability, the less the likelihood that the results happened purely by chance.

Imagine that the results of your experiment looked like the ones in Figure A.7. The mean IQs of the two groups differ by ten points: 75 for the experimental subjects and 65 for the controls. But look at the variability in the two distributions: there is almost none. All the children in the experimental group received a score within five points of 75; all the children in the control group received a score within five points of 65. It seems that some genuine effect is at work here. The IQ patterns in the two groups are distinctly different and are not the kinds of differences usually caused by chance.

Unfortunately, the results of most experiments are not this clear-cut. Far more often, the distributions look more like those in Figure A.8. In this figure, you can see that the mean difference in scores is still ten points, but now there is a sizable amount of variability in the two groups. In fact, some of the experimental subjects are doing no better than some of the controls, while some of the controls are scoring higher than some of those in the experimental program. Is a

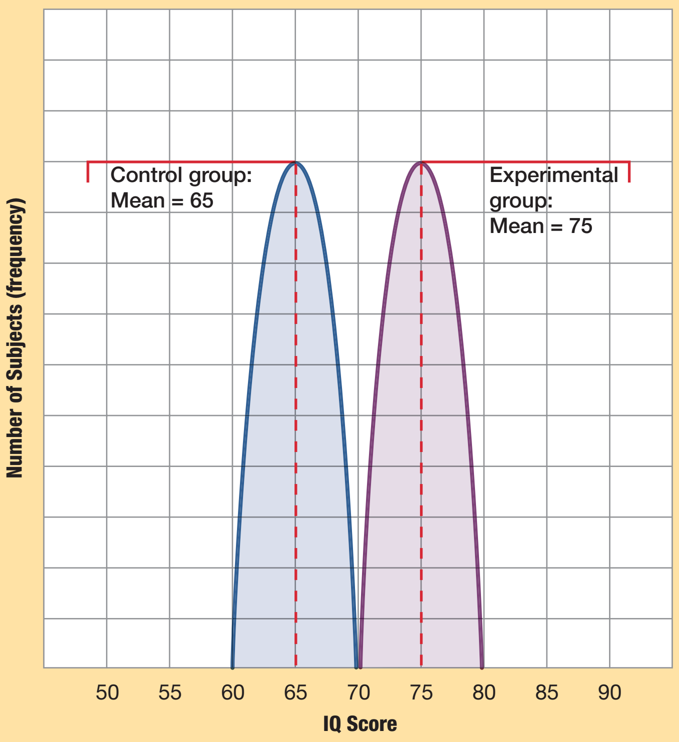


Figure A.7
In this distribution of IQ scores, the control group has a mean of 65; the experimental group, a mean of 75. When distributions in a study show this little variability and no overlap between the two curves, they are not very likely to have happened purely by chance.

mean difference of ten points in this case large enough to be considered reliable?

When should you use a *t* test?

The *t* test also considers how many subjects are included in the study. You should not put much faith in a comparison of educational programs that tries out each approach on only two or three children. There is too great a likelihood that such samples are not representative of the larger population from which they are drawn. Let's say that, in the hypothetical experiment we have been describing, you included 100 randomly selected children in each of the two groups. It is much less likely that samples of this size would be biased enough to distort the research's findings.

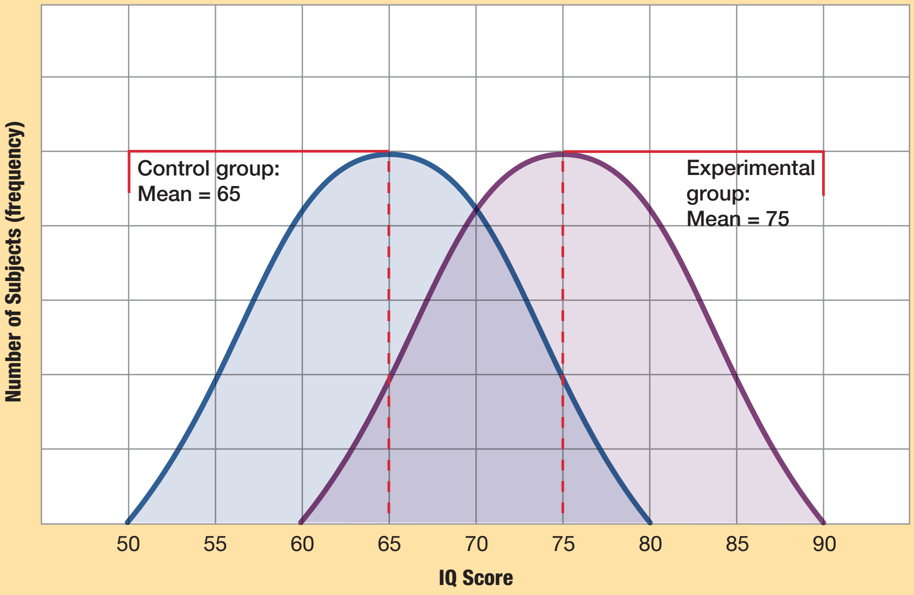
To learn the steps involved in actually performing the *t* test, please read the accompanying box.

Analysis of Variance

Not all data lend themselves to a *t* test, however. Often researchers want to compare the mean scores of more than two groups, or they want to make comparisons among groups that are classified in more than one way. (For instance, does age or sex have an effect on how much children benefit from our special education program?) In such cases another test of statistical significance is needed. This test is called an ***analysis of variance,*** or ***ANOVA*** for short. An analysis of variance is rather like a more complex *t* test. To learn more about the ANOVA technique, consult any introductory statistics text.

Figure A.8

This set of distributions is much more likely than the one in Figure A.7. The mean is still 65 for the control group and 75 for the experimental group. But now the variability of the distributions is substantially greater. There is also substantial overlap between the two curves. Is the mean difference in this case statistically significant? A *t* test can provide the answer.



How to Perform the *t* Test

The *t* test is an estimate of how reliable the difference between two means is. To determine the likelihood that the outcome occurred by chance, you first need to know the size of the mean difference (mean 1 minus mean 2). In general, the larger the mean difference, the less likely that it happened by chance alone. You also need to know the variance within each group.

The ***variance*** is a measure of the variability within the two distributions.

In general, the lower the variance, the less likely that chance alone caused the results. Finally, you need to know how many subjects are in the random samples. In general, the larger the samples, the less the likelihood of a purely chance explanation.

To calculate the *t* test just follow these steps:

1. Determine the mean of the scores for each group and subtract one from the other.
2. Go back to the box on standard deviation and work through that calculation for each of your distributions, stopping at step 4. This gives you the variance of each distribution.
3. Add the two variances.
4. Add the total number of subjects minus 2 (in our example 200 – 2 = 198).
5. Divide the summed variances by the number obtained in step 4 and take the square root.
6. Divide the mean difference between the two groups by the square root from step 5.

If the samples add up to more than 50 individuals, any value of *t* over 2 is statistically reliable more than 95% of the time.

Chi-Square

Sometimes the data psychologists collect do not consist of sets of scores with means or averages. Instead, the researchers have recorded who does what, or who falls into which of several categories. For instance, psychologists have found that chess players are more apt to be introverts than they are to be extroverts. Is this just a chance association? To answer such questions, statisticians often use the *chi (ky) square,* a test of statistical significance.

Suppose you are a psychologist and you want to study the usefulness of fear tactics in changing people's behavior. You randomly select 200 habitual smokers who are willing to participate in an experiment. You expose half to a 20-minute talk on the known health hazards of smoking, complete with graphic illustrations of diseased lungs and hearts. You expose the rest to a 20-minute talk on the history of tobacco. After the talks, the members of each group are given the opportunity to sign up for a free "quit smoking" clinic. Some people from each group sign up for the clinic; some do not. The easiest way to present their choices is with a 2 × 2 table, like the one set up in Table A.1.

Table A.2 shows how the distribution worked out in your study. Of the 100 subjects in your experimental group (the ones exposed to the fear tactics), 60 signed up for the quit-smoking clinic and 40 did not. Of the 100 subjects in the control group, 40 signed up for the free clinic and 60 did not. Is this difference in the distribution of choices statistically significant? The chi-square can be used to estimate the reliability of this difference.

The *chi-square* is a test of statistical significance that compares the actual observed distribution of people (or events) among various categories with the distribution expected purely on the basis of chance.

If people had made their decisions purely by chance—for instance, by the toss of a coin—the same number of people would be expected to sign up for the clinic in each of the two groups. The accompanying box gives a step-by-step description of how to do the chi-square calculation.

Table A.1: The Format of a 2 × 2 Table

Talk heard	Signed up for clinic	Didn't sign up	Row Total
Fear tactics			100
No fear tactics			100
Column totals			200 (grand total)

Table A.2: Study Results in Our Sample

Talk heard	Signed up for clinic	Didn't sign up	Row Total
Fear tactics	60	40	100
No fear tactics	40	60	100
Column totals	100	100	200 (grand total)

How to Calculate Chi-Square

Chi-square (χ^2) is an estimate of how sure we can be that a distribution of events or of people did not happen just by chance. In our example, chi-square calculates the *expected* number of people that a chance distribution would place in each of the categories represented by the four cells in the table. This expected number is then compared with the actual *observed* number of people in each of these categories, shown by cells (the data presented in Table A.2). If the difference between the expected and observed numbers is large enough, the distribution is not likely to have happened by chance alone.

Here are the steps in making the chi-square calculation:

1. Figure out how many people, by chance alone, would be likely to fall into the upper-left cell. To do this, multiply the first row total by the first column total (100 × 100) and divide by the grand total (200). The expected number is 50.

2. Subtract the expected number (50) from the observed number in the upper-left cell (60). The difference is 10 (60 – 50 = 10). Square the difference to eliminate negative signs (10 × 10 = 100) and divide the result by the expected number: 100 ÷ 50 = 2.

3. Repeat steps 1 and 2 for each of the four cells. In this example, the expected values are the same for each cell, but that won't always be true.

4. Add the four values you get from calculating the difference between the expected and observed number for each cell. This is the chi-square.

The reliability of the chi-square value must be looked up in a table. In this example, the fear-tactic subjects signed up for the clinic so much more often than the control subjects did that this distribution could have occurred by chance only two times in a hundred.

Summary Test

Descriptive Statistics

1. The tools that researchers use to analyze and summarize large amounts of data are called (a) ________________. Numbers that are used to present a collection of data in a brief yet meaningful form are (b) ________________ statistics, which are often used to present distributions of measurements and scores. The range of scores and the frequency of each one are called the (c) ________________; this is often presented in graphic form so the patterns can be seen at a glance.

2. When graphed, a normal distribution produces a curve that tapers off equally on either side from a central high point; this is called a (a) ________________ curve. This curve has the characteristic shape of a (b) ________________ and shows that most of the measurements fall near the center, with as many falling to one side as to the other. However, not all traits are distributed normally. If more data fall toward one side of the scale than toward the other, it is called a (c) ________________ distribution. Such distributions do not have symmetrical shapes when plotted; instead, they have a "tail" on one end. When there are fewer frequencies at the higher end of the horizontal scale (the tail is on the right), we say the distribution is skewed to the right or has a (d) ________________ skew. When there are fewer frequencies at the lower end of the horizontal scale (the tail is on the left), we say the distribution is skewed to the left or has a (e) ________________ skew.

3. Ways of describing what is "typical" within a given distribution are called measures of (a) ________________. The arithmetic average of all the individual measurements in a distribution is the (b) ________________. The score above and below which half the scores in the distribution fall is the (c) ________________. The measurement that occurs most often in a distribution is the (d)________________.

4. The extent to which scores in a distribution are spread out—in other words, how much scores vary from one another—is the measure of (a) ________________. The two most extreme scores at either end of a distribution indicate the range. The measure of variability that shows how widely all the scores in a distribution are scattered above and below the mean is called the (b) ________________.

Inferential Statistics

5. Because the influence of chance on scientific findings cannot be completely avoided, procedures are necessary to determine what conclusions can be properly inferred from a set of data; these procedures are called (a) ________________ statistics. If the likelihood that the results could have occurred purely by chance is small, researchers can reject the chance explanation and conclude that their findings are probably (b) ________________; that is, they would probably obtain similar results if they repeated the study over and over with different groups.

6. Different kinds of data require different tests of statistical significance. An estimate of reliability that takes the size of the mean difference and the variability in distributions into account is called the (a) ________________; it estimates how reliable the difference between two means is. In general, the greater the difference between (b) ________________, the less likely that the results happened by chance alone.

7. A measure of the variability within two distributions is called the (a) ________________. In general, the lower the variance, the less likely that chance alone caused the results. An analysis of variance, or (b) ________________ test, is similar to, but more complex than, the *t* test.

8. How sure we can be that a distribution of events or of people did not happen just by chance is measured by another test of statistical significance, called the ________________.

Answers: *1. (a) statistics, (b) descriptive, (c) frequency distribution; 2. (a) normal, (b) bell, (c) skewed, (d) positive, (e) negative; 3. (a) central tendency, (b) mean, (c) median, (d) mode; 4. (a) variability, (b) standard deviation; 5. (a) inferential, (b) reliable; 6. (a)* t *test, (b) means; 7. (a) variance, (b) ANOVA; 8. chi-square*

Glossary

A

ability tests Achievement tests, which measure what we have learned; aptitude tests, which measure our potential for learning or acquiring a specific skill; and intelligence tests, which measure our general potential to solve problems, think abstractly, and profit from experience.

absolute threshold The intensity level of a stimulus such that a person has a 50% chance of detecting it.

accommodation The process by which a person changes old methods to deal with or adjust to new situations.

achievement need The desire to set challenging goals and to persist in pursuing those goals in the face of obstacles, frustrations, and setbacks.

acquired immune deficiency syndrome *See* AIDS.

action potential A tiny electric current that is generated when positive sodium ions rush inside the axon. The enormous increase of sodium ions inside the axon causes the inside of the axon to reverse its charge: The inside becomes positive, while the outside becomes negative.

activation-synthesis theory of dreams The idea that dreaming represents the random and meaningless activity of nerve cells in the brain. According to this theory, the pons, an area in the brain, sends millions of random nerve impulses to the cortex; the cortex then tries to make sense of these signals by creating the feelings, imagined movements, perceptions, changing scenes, and meaningless images that we define as dreams.

actor-observer effect Our tendency, when we are behaving (or acting), to attribute our own behavior to situational factors but, when we are observing, to attribute another person's behavior to his or her personality traits or disposition.

acupuncture An ancient Chinese procedure for the relief of pain, in which a trained practitioner inserts thin needles into various points on the body's surface, often far from the site of the pain, and then manually twirls or electrically stimulates the needles.

adaptation A feature of a species that provides it with improved function, such as a behavior that helps an organism better escape a predator or a physical characteristic that provides an organism with an advantage. Also, the decreasing response of the sensory organs as they are exposed to a continuous level of stimulation.

adaptation level theory The idea that we quickly become accustomed to receiving some good fortune (money, job, car, degree). We take the good fortune for granted within a short period of time and, as a result, the initial impact of our good fortune fades and contributes less to our long-term level of happiness.

adaptive genes Genes for traits that help an organism survive and reproduce.

adaptive theory A theory suggesting that sleep evolved as a survival mechanism, since it prevented early humans and animals from wasting energy and exposing themselves to the dangers of nocturnal predators.

adaptive value The usefulness of certain abilities or traits that have evolved in animals or humans that tend to increase their chances of survival, such as the ability to find food, acquire mates, and avoid illness and injury.

addiction A behavioral pattern of drug abuse that is marked by an overwhelming and compulsive desire to obtain and use the drug. Even after stopping, the addict has a tendency to relapse and begin using the drug again.

adjustment disorder A condition in which a person is unable to cope with, or adjust to, a major life change. The condition includes emotional and behavioral symptoms.

adolescence A developmental period, lasting from about the ages of 12 to 18, that marks the end of childhood and the beginning of adulthood; it is a transitional period of considerable biological, cognitive, social, and personality changes.

adrenal glands Structures in the endocrine system. The adrenal cortex (outer part) secretes hormones that regulate sugar and salt balances and help the body resist stress; they are also responsible for the growth of pubic hair, a secondary sexual characteristic. The adrenal medulla (inner part) secretes two hormones that arouse the body to deal with stress and emergencies: epinephrine (adrenaline) and norepinephrine (noradrenaline).

affective neuroscience approach The study of the underlying neural bases of mood and emotion by focusing on the brain's neural circuits that evaluate stimuli and produce or contribute to experiencing and expressing different emotional states.

afferent neurons Neurons that carry information from the senses to the spinal cord; also called sensory neurons.

afterimage A visual image that continues after the original stimulus is removed.

age regression In hypnosis, the suggestion that subjects regress, or return, to an earlier time in their lives—for example, to early childhood.

aggression Any behavior directed toward another that is intended to cause harm.

aging process Changes caused by a combination of certain genes and proteins that interfere with organ functioning and by the natural production of toxic molecules (free radicals) that, in turn, cause random damage to body organs and to DNA (the building blocks of life). Such damage eventually exceeds the body's ability to repair itself and results in greater susceptibility to diseases and death.

agoraphobia An anxiety about being in places or situations from which escape might be difficult or embarrassing if a panic attack or paniclike symptoms (sudden dizziness or onset of diarrhea) were to occur.

AIDS (acquired immune deficiency syndrome) A life-threatening condition that, by the latest definition, is present when the individual is HIV positive and has a level of T-cells (CD4 immune cells) of no more than 200 per cubic milliliter of blood (one-fifth the level of a healthy person) or has developed one or more of 26 specified illnesses (including recurrent pneumonia and skin cancer).

alarm stage In the general adaptation syndrome, our initial reaction to stress, marked by activation of the fight-flight response, which causes physiological arousal.

alcohol (ethyl alcohol) A psychoactive drug classified as a depressant; it depresses activity of the central nervous system. Alcohol causes friendliness and loss of inhibitions at low doses, impairs drinkers' social judgment and understanding at medium doses, and seriously impairs motor coordination, cognitive abilities, decision making, and speech at higher doses. Very high doses may result in coma and death.

alcoholism A problem involving addiction to alcohol. An alcoholic is a person who has drunk heavily for a long period of time, is addicted to and has an intense craving for alcohol, and, as a result, has problems in two or three major life areas (social, personal, and financial areas, for example).

algorithms Rules that, if followed correctly, will eventually lead to the solution of a problem.

all-or-none law The fact that, once a nerve impulse starts in a small segment at the very beginning of the axon, it will continue at the same speed, segment by segment, to the very end of the axon.

alpha stage In sleep, a stage marked by feelings of being relaxed and drowsy, usually with the eyes closed. Alpha waves have low amplitude and high frequency (8–12 cycles per second).

altered state of consciousness An awareness that differs from normal consciousness; such awareness may be produced by using any number of procedures, such as meditation, psychoactive drugs, hypnosis, or sleep deprivation.

altered state theory of hypnosis The idea that hypnosis is not a trancelike state but rather an altered state of consciousness, during which a person experiences different sensations and feelings. No physiological measures have been found to indicate that a person is in a trance. For another view of hypnosis, see the sociocognitive theory of hypnosis.

altruism Helping or doing something, often at a cost or risk, for reasons other than the expectation of a material or social reward.

Alzheimer's disease A disorder that usually begins after people reach age 50 and is always fatal; it results from widespread damage to the brain, including the hippocampus, and produces deterioration in personality, emotions, cognitive processes, and memory.

Ames room A viewing environment, designed by Albert Ames, that demonstrates how our perception of size may be distorted by manipulating our depth cues.

amnesia Memory loss that may occur after damage to the brain (temporary or permanent), following drug use, or after severe psychological stress.

amniocentesis A medical test performed between weeks 14 and 20 of pregnancy. A long needle is inserted through the mother's abdominal muscles into the amniotic fluid surrounding the fetus. By withdrawing and analyzing fetal cells in the fluid, doctors can identify a number of genetic problems.

amygdala A structure in the limbic system that is located in the tip of the temporal lobe and is involved in forming, recognizing, and remembering emotional experiences and facial expressions.

anal stage Freud's second psychosexual stage, lasting from the ages of about 1½ to 3. In this stage, the infant's pleasure seeking is centered on the anus and its functions of elimination.

analogy A strategy for finding a similarity between a new situation and an old, familiar situation.

androgens Male sex hormones.

anencephaly The condition of being born with little or no brain. If some brain or nervous tissue is present, it is totally exposed and often damaged because the top of the skull is missing. Survival is usually limited to days; the longest has been 2 months.

animal model An approach to studying some human problem, situation, or disease by observing, testing, and measuring animals' behavioral, physiological, or neurological changes under conditions that closely approximate it.

anorexia nervosa A serious eating disorder characterized by refusing to eat and not maintaining weight at 85% of what is expected, having an intense fear of gaining weight or becoming fat, and missing at least three consecutive menstrual cycles. Anorexics also have a disturbed body image: They see themselves as fat even though they are very thin.

anterior pituitary The front part of the pituitary gland, a key component of the endocrine system. It regulates growth through the secretion of growth hormone and produces hormones that control the adrenal cortex, pancreas, thyroid, and gonads.

anticipatory nausea Feelings of nausea that are elicited by stimuli associated with nausea-inducing chemotherapy treatments. Patients experience nausea in anticipation of their treatment. Researchers believe that anticipatory nausea occurs through classical conditioning.

antidepressant drugs Drugs used to combat depression. They act by increasing levels of a specific group of neurotransmitters (monoamines, such as serotonin) that are believed to be involved in the regulation of emotions and moods.

antipsychotic drugs *See* neuroleptic drugs.

antisocial personality disorder A pattern of disregarding or violating the rights of others without feeling guilt or remorse. It is found in 3% of the population, predominantly in males.

anxiety An unpleasant state that is associated with feelings of uneasiness, apprehension, and heightened physiological arousal, such as increased heart rate and blood pressure. According to Freud, anxiety arises when there is an unconscious conflict between the id's and superego's desires regarding how to satisfy a need; the ego, caught in the middle, reacts by creating a feeling of anxiety. More modern theories of anxiety are based on conditioned emotional responses and observational learning.

apparent motion An illusion that a stimulus or object is moving in space when, in fact, it is stationary. This illusion is created by rapidly showing a series of stationary images, each of which has a slightly different position or posture than the one before.

approach A focus or perspective that may use a particular research method or technique. Seven approaches to understanding behavior are the biological, cognitive, behavioral, psychoanalytic, humanistic, cross-cultural, and evolutionary.

approach-approach conflict Having to choose between two situations that both have pleasurable consequences.

approach-avoidance conflict The conflict that arises in a single situation that has both pleasurable and disagreeable aspects.

arousal-cost-reward model of helping The idea that we make decisions to help by calculating the costs and rewards of helping.

assimilation The process by which a child uses old methods or experiences to deal with new situations and then incorporates the new information into his or her existing knowledge.

atmospheric perspective In three-dimensional vision, a monocular depth cue that comes into play in the presence of dust, smog, or water vapor. Hazy objects are interpreted as being farther away.

attachment A close fundamental emotional bond that develops between the infant and his or her parent or caregiver.

attention-deficit/hyperactivity disorder (ADHD) A condition diagnosed on the basis of the occurrence of certain behavioral problems, rather than medical tests. A child must have six or more symptoms of inattention (such as making careless mistakes in schoolwork) and six or more symptoms of hyperactivity (such as fidgeting or talking excessively). These symptoms should have been present from an early age, persisted for at least six months, and contributed to maladaptive development.

attitude Any belief or opinion that includes a positive or negative evaluation of some object, person, or event and that predisposes us to act in a certain way toward that object, person, or event.

attributions Our explanations of the causes of events, other people's behaviors, and our own behaviors.

atypical neuroleptic drugs Neuroleptic drugs that somewhat lower levels of dopamine but, more important, reduce levels of other neurotransmitters, especially serotonin. One group of these drugs is the benzamides, such as clozapine. These drugs primarily reduce positive symptoms and may slightly improve negative symptoms.

auditory association area An area directly below the primary auditory cortex that receives and transforms meaningless auditory sensations into perceptions or meaningful sounds, such as melodies or words.

auditory canal A long tube in the ear that funnels sound waves down its length so that the waves strike a thin, taut membrane—the eardrum, or tympanic membrane.

auditory nerve A band of fibers that carries impulses (electrical signals) from the cochlea to the brain, resulting in the perception of sounds.

authoritarian parents Parents who attempt to shape, control, and evaluate the behaviors and attitudes of their children in accordance with a set standard of conduct, usually an absolute standard that comes from religious or respected authorities.

authoritative parents Parents who attempt to direct their children's activities in a rational and intelligent way. They are supporting, loving, and committed, encourage verbal give-and-take, and discuss their rules and policies with their children.

autism A condition marked by especially abnormal or impaired development in social interactions, spoken language, and sensory-motor systems. Autistics characteristically have few activities or interests and spend long periods of time repeating the same ritualistic physical behaviors. Signs of autism begin in a child's first three years.

automatic encoding The transfer of information from short-term into long-term memory without any effort and usually without any awareness.

automatic processes Activities that require little awareness, take minimal attention, and do not interfere with other ongoing activities.

autonomic nervous system That portion of the peripheral nervous system that regulates heart rate, breathing, blood pressure, digestion, hormone secretion, and other functions, as well as maintains the body in a state of optimal balance, or homeostasis. It usually functions without conscious effort, which means that only a few of its responses, such as breathing, can also be controlled voluntarily. Its two subdivisions are the sympathetic division and the parasympathetic division.

availability heuristic A rule of thumb by which we rely on information that is more prominent or easily recalled and overlook other information that is available but less prominent or notable.

avoidance-avoidance conflict Having to choose between two situations that both have disagreeable consequences.

axon A single threadlike structure within the neuron. It extends from, and carries signals away from, the cell body to neighboring neurons, organs, or muscles.

axon membrane The axon wall, which contains chemical gates that may be opened or closed to control the inward and outward flow of electrically charged particles called ions.

B

babbling The first stage in acquiring language, in which infants, at about 6 months of age, begin to make one-syllable sounds such as "dee-dee-dee" or "ba-ba-ba." Many of these sounds are common across languages.

Bandura's social cognitive theory A personality theory that assumes that personality development, growth, and change are influenced by four distinctively human cognitive processes: highly developed language ability, observational learning, purposeful behavior, and self-analysis. Bandura emphasizes the importance of learning through observation, imitation, and self-reward in the development of social skills, interactions, and behaviors. He contends that we can learn new social skills without performing any observable behaviors or receiving any external rewards. *See also* social cognitive theory.

Barnum principle A technique used in horoscopes and elsewhere, in which a number of traits are listed in such a general way that almost everyone who reads them thinks that these traits apply specifically to him or her. This technique was named after circus owner P. T. Barnum.

basal ganglia A group of structures in the center of the brain that are involved in regulating movements. To function properly, neurons in the basal ganglia must have a sufficient supply of the neurotransmitter dopamine.

basic rules of grammar Rules for combining nouns, verbs, and other parts of speech into meaningful sentences.

basilar membrane A membrane within the cochlea that contains the auditory receptors, or hair cells.

Beck's cognitive theory of depression The idea that when we are depressed, automatic negative thoughts that we rarely notice occur continuously throughout the day. These negative thoughts distort how we perceive and interpret the world and thus influence our behaviors and feelings, which in turn contribute to our feelings of depression.

Beck's cognitive therapy *See* cognitive therapy.

behavior modification A treatment or therapy that changes or modifies problems or undesirable behaviors by using learning principles based on operant conditioning, classical conditioning, and social cognitive learning.

behavior therapy A form of psychotherapy in which disruptive behaviors are changed and human functioning is improved on the basis of principles of classical and operant conditioning. It focuses on changing particular behaviors rather than on the underlying mental events or possible unconscious factors. Sometimes called behavior modification or cognitive-behavioral therapy.

behavioral approach A psychological viewpoint that analyzes how organisms learn new behaviors or modify existing ones, depending on whether events in their environments reward or punish these behaviors. Historically, as founded by John B. Watson, the behavioral approach emphasized the objective, scientific analysis of observable behaviors.

behavioral genetics The study of how inherited or genetic factors influence and interact with psychological factors to shape our personality, intelligence, emotions, and motivation and also how we behave, adapt, and adjust to our environment.

benzodiazepines Minor tranquilizers (Librium, Valium, Xanax, Dalmane, Halcion) that reduce anxiety and stress. They are frequently prescribed for the short-term (3 or 4 weeks) treatment of insomnia. Side effects associated with high doses or prolonged use include daytime drowsiness, loss of memory, tolerance, and dependency.

Binet-Simon Intelligence Scale The world's first standardized intelligence test, containing items arranged in order of increasing difficulty. The items measured vocabulary, memory, common knowledge, and other cognitive abilities.

binocular depth cues In three-dimensional vision, depth cues that depend on the movement of both eyes (*bi* means "two"; *ocular* means "eye").

biofeedback A training procedure through which a person is made aware of his or her physiological responses, such as muscle activity, heart rate, blood pressure, or temperature, and then tries to increase or decrease these physiological responses.

biological approach A psychological viewpoint that examines how our genes, hormones, and nervous systems interact with our environments to influence learning, personality, memory, motivation, emotions, coping techniques, and other traits and abilities.

biological clock The body's internal timing device that is genetically set to regulate various physiological responses for certain periods of time.

biological factors Innate tendencies or predispositions that may either facilitate or inhibit certain kinds of learning.

biological factors underlying depression Genetic, neurological, chemical, and physiological components that may predispose or put someone at risk for developing a mood disorder.

biological hunger factors Physiological changes in blood chemistry and signals from digestive organs that provide feedback to the brain, which, in turn, triggers us to eat or stop eating.

biological needs Physiological requirements that are critical to our survival and physical well-being.

biological sex factors The actions of sex hormones, which are involved in secondary sexual characteristics (facial hair, breasts), sexual motivation (more so in animals than in humans), and the development of ova and sperm.

BioPsychoSocial model The representation of adolescent development as a process that occurs simultaneously on many levels and includes sexual, cognitive, social, and personality changes that interact and influence each other.

biosocial theory A theory that emphasizes social and cultural forces; it says that differences in sexual activities and values for selecting mates developed from traditional cultural divisions of labor: Women were primarily childbearers and homemakers, while men were primarily providers and protectors.

bipolar I disorder A mood disorder characterized by fluctuations between episodes of depression and mania. A manic episode goes on for at least a week, during which a person is unusually euphoric, cheerful, and high and has at least three of the following symptoms: has great self-esteem, has little need of sleep, speaks rapidly and frequently, has racing thoughts, is easily distracted, and pursues pleasurable activities. Formerly called manic-depressive illness.

bisexual orientation A pattern of sexual arousal by persons of either sex.

borderline personality disorder A pattern of instability in personal relationships, self-image, and emotions as well as impulsive behavior.

brightness constancy Our tendency to perceive brightness as remaining the same in changing illumination.

Broca's aphasia An inability to speak in fluent sentences while retaining the ability to understand written or spoken words. It is caused by damage to Broca's area.

Broca's area An area usually located in the left frontal lobe that is necessary for combining sounds into words and arranging words into meaningful sentences. *See* Broca's aphasia.

bulimia nervosa An eating disorder characterized by a minimum of two binge-eating episodes per week for at least three months; fear of not being able to stop eating; regularly engaging in vomiting, use of laxatives, or rigorous dieting and fasting; and excessive concern about body shape and weight.

burnout Feelings of doing poorly at one's job, physically wearing out, and becoming emotionally exhausted due to intense involvement with people who demand too much of one's time and energy and provide too little reward or satisfaction.

bystander effect The phenomenon in which an individual feels inhibited from taking some action because of the presence of others.

C

caffeine A mild stimulant that produces dilation of blood vessels, increased secretion of stomach acid, and moderate physiological arousal. Psychological effects include a feeling of alertness, decreased fatigue and drowsiness, and improved reaction times. Caffeine, which is present in coffee, tea, chocolate, and other foods, can be addictive, especially in higher doses.

case study An in-depth analysis of the thoughts, feelings, beliefs, experiences, behaviors, or problems of an individual. This research method offers little opportunity to control or manipulate situations or variables.

catatonic schizophrenia A subcategory of schizophrenia characterized by periods of wild excitement and periods of rigid, prolonged immobility; sometimes the person assumes the same frozen posture for hours on end.

catharsis A psychological process through which anger or aggressive energy is released by expressing or letting out powerful negative emotions. Freud's view that catharsis can be helpful in reducing aggression is not supported by most research.

cell body For neurons, a relatively large, egg-shaped structure that provides fuel, manufactures chemicals, and maintains the entire neuron in working order; also called the soma.

central cues Hunger cues associated with the activity of chemicals and neurotransmitters in different areas of the brain.

central nervous system Neurons located in the brain and spinal cord. From the bottom of the brain emerges the spinal cord, which is made up of neurons and bundles of axons and dendrites that carry information back and forth between the brain and the body. Neurons in the central nervous system normally have almost no capacity to regrow or regenerate if damaged or diseased.

central route for persuasion Presenting information with strong arguments, analyses, facts, and logic.

cephalocaudal principle The rule that parts of the body closer to the infant's head develop before parts closer to the feet.

cerebellum A region of the hindbrain that is involved in coordinating movements but not in initiating voluntary movements. It is also involved in cognitive functions, such as short-term memory, following rules, and carrying out plans. Surprising new evidence suggests that the cerebellum is also involved in learning to perform timed motor responses, such as those required in playing games or sports.

challenge appraisal Our conclusion that we have the potential for gain or personal growth in a particular situation but that we also need to mobilize our physical energy and psychological resources to meet the challenging situation.

chi-square A test of statistical significance that compares the actual observed distribution of people (or events) among various categories with the distribution expected purely on the basis of chance.

child abuse and neglect Inadequate care or acts by the parent(s) (physical or emotional abuse) that put a child in danger, cause physical harm or injury, or involve sexual molestation.

Chomsky's theory of language The idea that all languages share a common universal grammar and that children inherit a mental program to learn this universal grammar. This theory includes the concepts of deep structure and surface structure and of transformational rules to convert from one to the other.

chromosome A hairlike structure that contains tightly coiled strands of deoxyribonucleic acid (DNA). Each cell of the human body (except for the sperm and egg) contains 46 chromosomes, arranged in 23 pairs.

chunking Combining separate items of information into a larger unit, or chunk, and then remembering chunks of information rather than individual items; a technique of memory enhancement.

circadian rhythm A biological clock that is genetically programmed to regulate physiological responses within a time period of 24 or 25 hours (about a day); one example is the sleep-wake cycle.

clairvoyance The ability to perceive events or objects that are out of sight.

classical conditioning A kind of learning in which a neutral stimulus acquires the ability to produce a response that was originally produced by a different stimulus.

client-centered therapy An approach developed by Carl Rogers that assumes that each person has an actualizing tendency—that is, a tendency to develop his or her own potential; the therapist's task is to show compassion and positive regard in helping the client reach his or her potential. Also called person-centered therapy.

clinical and counseling psychology The assessment and treatment of people who have psychological problems, such as grief, anxiety, or stress.

clinical assessment A systematic evaluation of an individual's various psychological, biological, and social factors, as well as the identification of past and present problems, stressors, and other cognitive and behavioral symptoms.

clinical diagnosis A process of determining how closely an individual's specific symptoms match those that define a particular mental disorder.

clinical interview In assessment, a method of gathering information about relevant aspects of a person's past as well as current behaviors, attitudes, emotions, and details of present difficulties or problems. Some clinical interviews are unstructured, which means that they have no set questions; others are structured, which means that they follow a standard format of asking the same questions.

clinical psychologist An individual who has a PhD, has specialized in the clinical subarea, and has spent an additional year in a supervised therapy setting to gain experience in diagnosing and treating a wide range of abnormal behaviors. To train as a clinical psychologist usually requires 4–6 years of work after obtaining a college degree.

closure rule A perceptual rule stating that, in organizing stimuli, we tend to fill in any missing parts of a figure and see the figure as complete.

cocaine A stimulant produced from the leaves of the coca plant. Its physiological and behavioral effects are very similar to those of amphetamine: It produces increased heart rate and blood pressure, enhanced mood, alertness, increased activity, decreased appetite, and diminished fatigue. At higher doses, it can produce anxiety, emotional instability, and suspiciousness.

cochlea A coiled, fluid-filled structure in the inner ear that contains the receptors for hearing. Its function is transduction—transforming vibrations into nerve impulses that are sent to the brain for processing into auditory information.

cochlear implant A miniature electronic device that is surgically implanted into the cochlea to restore hearing in those with neural deafness. It converts sound waves into electrical signals, which are fed into the auditory nerve and hence reach the brain for processing.

cognitive appraisal theory The idea that our interpretation or appraisal of a situation is often the primary cause of emotions.

cognitive approach *See* cognitive psychology.

cognitive-behavioral therapy A treatment for phobias and other mental disorders based on a combination of two methods: changing negative, unhealthy, or distorted thoughts and beliefs by substituting positive, healthy, and realistic ones; and changing limiting or disruptive behaviors by learning and practicing new skills to improve functioning. Sometimes called behavior therapy.

cognitive development How a person perceives, thinks, and gains an understanding of his or her world through the interaction and influence of genetic and learned factors.

cognitive developmental theory The idea that, as they develop mental skills and interact with their environments, children learn one set of rules for male behavior and another set of rules for female behavior.

cognitive dissonance A state of unpleasant psychological tension that motivates us to reduce our cognitive inconsistencies by making our beliefs more consistent with one another.

cognitive-emotional-behavioral and environmental factors The factors that contribute to the development of mental disorders, including deficits in cognitive processes, such as having unusual thoughts and beliefs; deficits in processing emotional stimuli, such as under- or overreacting to emotional situations; behavioral problems, such as lacking social skills; and environmental challenges, such as dealing with stressful situations.

cognitive factors According to social cognitive theory, factors that include our beliefs, expectations, values, intentions, and social roles—all of which help to shape our personalities.

cognitive factors in motivation The influence of individuals' evaluations or perceptions of a situation on their willingness to work.

cognitive interview A technique for questioning eyewitnesses and others by having them imagine and reconstruct the details of an event, report everything they remember without holding anything back, and narrate the event from different viewpoints.

cognitive learning A kind of learning that involves mental processes, such as attention and memory; may proceed through observation or imitation; and may not involve any external rewards or require the person to perform any observable behaviors.

cognitive map A mental representation of the layout of an environment and its features.

cognitive miser model The idea that, in making attributions, people feel they must conserve time and effort by taking cognitive shortcuts.

cognitive neuroscience An approach to studying cognitive processes that involves taking pictures of the structures and functions of the living brain during the performance of a wide variety of mental or cognitive processes, such as thinking, planning, naming, and recognizing objects.

cognitive perspective The theory that an organism learns a predictable relationship between two stimuli such that the occurrence of one stimulus (neutral stimulus) predicts the occurrence of another (unconditioned stimulus). In other words, classical conditioning occurs because the organism learns what to expect. Formerly called information theory.

cognitive psychology The study of how we process, store, retrieve, and use information and how cognitive processes influence what we attend to, perceive, learn, remember, believe, feel, and do.

cognitive social psychology A subarea of social psychology that focuses on how cognitive processes, such as perceiving, retrieving, and interpreting information about social interactions and events, affect emotions and behaviors and how emotions and behaviors affect cognitions.

cognitive therapy An approach to therapy that focuses on the role of thoughts in our emotions and actions. The widely used version developed by Aaron Beck assumes that we have automatic negative thoughts that we typically say to ourselves without much notice. By continuously repeating these automatic negative thoughts, we color and distort how we perceive and interpret the world and influence how we behave and feel. The goal of the therapy is to change these automatic negative thoughts.

collective unconscious According to Jung, ancient memory traces and symbols that are passed on by birth and are shared by all people in all cultures.

color blindness Inability to distinguish between two or more shades in the color spectrum. There are several kinds of color blindness. *See* monochromats and dichromats.

color constancy Our tendency to perceive colors as remaining stable despite differences in lighting.

commitment In Sternberg's triangular theory of love, the component of love associated with making a pledge to nourish the feelings of love and to actively maintain the relationship.

common factors A basic set of procedures and experiences shared by different therapies that account for those therapies' comparable effectiveness despite their different fundamental principles and techniques. Common factors include the growth of a supportive and trusting relationship between therapist and client and the accompanying development of an accepting atmosphere in which the client feels willing to admit problems and is motivated to work on changing.

communication The ability to use sounds, smells, or gestures to exchange information.

community mental health centers Government-sponsored centers that offer low-cost or free mental health care to members of the surrounding community, especially the underprivileged. The services may include psychotherapy, support groups, or telephone crisis counseling.

companionate love A condition associated with trusting and tender feelings for someone whose life is closely bound up with one's own.

compliance A kind of conformity in which we give in to social pressure in our public responses but do not change our private beliefs.

concept A way to group objects, events, or characteristics on the basis of some common property they all share.

conception The process in which one of the millions of sperm penetrates the ovum's outside membrane; also called fertilization. After penetration, the outside membrane changes and becomes impenetrable to the millions of remaining sperm.

concrete operations stage The third of Piaget's cognitive stages, lasting from about the ages of 7 to 11 years. During this stage, children can perform a number of logical mental operations on concrete objects that are physically present.

conditional positive regard Positive regard that depends on our behaving in certain ways—for example, living up to or meeting others' standards.

conditioned emotional response The feeling of some positive or negative emotion, such as happiness, fear, or anxiety, when experiencing a stimulus that previously accompanied a pleasant or painful event. This is an example of classical conditioning.

conditioned response (CR) A response elicited by the conditioned stimulus; it is similar to the unconditioned response but not identical in magnitude or amount.

conditioned stimulus (CS) A formerly neutral stimulus that has acquired the ability to elicit a response previously elicited by the unconditioned stimulus.

conduct disorder A repetitive and persistent pattern of aggressive behavior that has been going on for at least a year and that violates the established social rules or the rights of others. Problems may include threatening to harm people, abusing or killing animals, destroying property, being deceitful, or stealing.

conduction deafness Deafness caused by wax in the auditory canal, injury to the tympanic membrane, or malfunction of the ossicles.

cones Photoreceptors that contain three chemicals called opsins, which are activated in bright light and allow us to see color. Unlike rods, cones are wired individually to neighboring cells; this one-on-one system of relaying information allows us to see fine details.

conflict The feeling we experience when we must decide between two or more incompatible choices.

conformity Any behavior you perform because of group pressure, even though that pressure might not involve direct requests.

conscious thoughts Wishes, desires, or thoughts that we are aware of, or can recall, at any given moment.

consciousness An individual's different levels of awareness of his or her thoughts and feelings. Creating images in the mind, following thought processes, and having unique emotional experiences are all part of consciousness.

consensus In making attributions, determining whether other people engage in the same behavior in the same situation.

conservation The idea that even though the shape of some object of substance is changed, the total amount remains the same.

consistency In making attributions, determining whether an individual engages in a certain behavior every time he or she is in a particular situation.

contiguity theory The view that classical conditioning occurs because two stimuli (the neutral stimulus and the unconditioned stimulus) are paired close together in time (are contiguous). Eventually, as a result of this contiguous pairing, the neutral stimulus becomes the conditioned stimulus, which elicits the conditioned response.

continuity rule A perceptual rule stating that, in organizing stimuli, we tend to favor smooth or continuous paths when interpreting a series of points or lines.

continuous reinforcement The simplest reinforcement schedule, in which every occurrence of the operant response results in delivery of the reinforcer.

continuum of consciousness The wide range of human experiences, from being acutely aware and alert to being totally unaware and unresponsive.

control group In an experiment, subjects who undergo all the same procedures as the experimental subjects do, except that the control subjects do not receive the treatment.

Control Question Technique A lie-detection procedure in which the examiner asks two kinds of questions: neutral questions that elicit little emotional response and critical questions that are designed to elicit greater emotional responses. The person answers only "Yes" or "No" to the questions and, if guilty, is expected to show a greater emotional response to the critical questions than to the neutral questions.

controlled processes Activities that require full awareness, alertness, and concentration to reach some goal. Because of the strongly focused attention they require, controlled processes often interfere with other ongoing activities.

conventional level Kohlberg's intermediate level of moral reasoning. It consists of two stages: At stage 3, moral decisions are guided most by conforming to the standards of others we value; at stage 4, moral reasoning is determined most by conforming to the laws of society.

convergence In three-dimensional vision, a binocular cue for depth perception based on signals sent from the muscles that turn the eyes. To focus on near or approaching objects, these muscles turn the eyes inward, toward the nose. The brain uses the signals sent by these muscles to determine the distance of the object.

convergent thinking Beginning with a problem and coming up with a single correct solution.

conversion disorder A type of somatoform disorder characterized by unexplained and significant physical symptoms—headaches, nausea, dizziness, loss of sensation, paralysis—that suggest a real neurological or medical problem but for which no physical or organic cause can be identified. Anxiety or emotional distress is apparently converted to symptoms that disrupt physical functioning.

cornea The rounded, transparent covering over the front of the eye. As the light waves pass through the cornea, its curved surface bends, or focuses, the waves into a narrower beam.

correlation An association or relationship between the occurrence of two or more events.

correlation coefficient A number that indicates the strength of a relationship between two or more events. The closer the number is to –1.00 or +1.00, the greater is the strength of the relationship.

cortex A thin layer of cells that essentially covers the entire surface of the forebrain. The cortex consists of the frontal, parietal, occipital, and temporal lobes, whose control centers allow us to carry out hundreds of cognitive, emotional, sensory, and motor functions.

counseling psychologist An individual who has a PhD in psychology or education and whose training included work in a counseling setting. Counseling psychologists generally have a less extensive research background than clinical psychologists and work in real-world settings, such as schools, industry, and private practice. Whereas clinical psychologists treat mental disorders, counseling psychologists deal largely with problems of living. To train as a counseling psychologist generally takes 4–6 years after obtaining a bachelor's degree.

counterattitudinal behavior Taking a public position that runs counter to your private attitude.

covariation model A model developed by Harold Kelley that may be used in deciding between internal and external attributions. The model says that, in determining attributions, we should look for factors that are present when the behavior occurs and factors that are absent when the behavior does not occur.

creative individual Someone who regularly solves problems, fashions products, or defines new questions that make an impact on his or her society.

creative thinking A combination of flexibility in thinking and reorganization of understanding to produce innovative ideas and new solutions.

critical language period A period of time from infancy to adolescence when language is easiest to learn; in the period after adolescence through adulthood, language is more difficult to learn.

critical period In imprinting, a relatively brief time during which learning is most likely to occur. Also called the sensitive period.

cross-cultural approach A psychological viewpoint that studies the influence of cultural and ethnic similarities and differences on psychological and social functioning.

cross-sectional method A research design in which several groups of different-aged individuals are studied at the same time.

crowd A large group of persons, most of whom are unacquainted.

cultural bias In testing, the situation in which the wording of the questions and the experiences on which they are based are more familiar to members of some social groups than to others.

cultural-familial retardation Mental retardation that results from greatly impoverished environments, with no evidence of genetic or brain damage.

cultural influences Pervasive pressures that encourage members of a particular society or ethnic group to conform to shared behaviors, values, and beliefs.

culture-specific disorder A pattern of mental illness or abnormal behavior that is unique to an ethnic or cultural population and does not match the Western classifications of mental disorders.

cumulative record A continuous written record that shows an organism's responses and reinforcements.

curare A drug that enters the bloodstream, reaches the muscles, and blocks receptors on the muscles. As a result, acetylcholine, the neurotransmitter that normally activates muscles, is blocked, and the muscles are paralyzed.

cybertherapy Therapy delivered over the Internet.

D

DARE (Drug Abuse Resistance Education) A drug awareness program taught in the classroom by trained, uniformed police officers. It is based on the idea of using social influence and role-playing to discourage adolescents from starting drug use and to encourage them to refuse drugs in the future.

daydreaming An activity that requires a low level of awareness, often occurs during automatic processes, and involves fantasizing or dreaming while awake.

debriefing A procedure administered to subjects after an experiment to minimize any potential negative effects. It includes explaining the purpose and method of the experiment, asking the subjects their feelings about having been in the experiment, and helping the subjects deal with possible doubts or guilt that arises from their behaviors in the experiments.

decibel A unit to measure loudness. The human range for hearing is from 0 decibels, which is absolutely no sound, to 140 decibels, which can produce pain and permanent hearing loss.

decision-stage model of helping The idea that we go through five stages in deciding to help: (1) we notice the situation; (2) we interpret it as one in which help is needed; (3) we assume personal responsibility; (4) we choose a form of assistance; and (5) we carry out that assistance.

declarative memory Memories of facts or events, such as scenes, stories, words, conversations, faces, or daily events. We are aware of these kinds of memories and can retrieve them.

deep structure According to Chomsky, a sentence's underlying meaning that is not spoken but is present in the mind of the listener.

defense mechanisms Freudian processes that operate at unconscious levels to help the ego reduce anxiety through self-deception.

deficiency needs Physiological needs (food and sleep) and psychological needs (safety, belongingness, and esteem) that we try to fulfill if they are not met.

deindividuation The increased tendency for subjects to behave irrationally or perform antisocial behaviors when there is less chance of being personally identified.

deinstitutionalization The release of mental patients from mental hospitals and their return to the community to develop more independent and fulfilling lives.

delay of gratification Voluntarily postponing an immediate reward to persist in completing a task for the promise of a future reward.

dendrites Branchlike extensions that arise from the cell body; they receive signals from other neurons, muscles, or sense organs and pass them to the cell body.

denial Refusal to recognize some anxiety-provoking event or piece of information.

dependency A change in the nervous system such that a person addicted to a drug now needs to take it to prevent the occurrence of painful symptoms.

dependent personality disorder A pattern of being submissive and clingy because of an excessive need to be taken care of. It is found in 2% of the population.

dependent variable In an experiment, one or more of the subjects' behaviors that are used to measure the potential effects of the treatment or independent variable.

depth perception In visual perception, the ability of the eye and brain to add a third dimension, depth, to visual perceptions, even though the images projected on our retina have only two dimensions, height and width.

descriptive statistics Numbers used to present a collection of data in a brief yet meaningful form.

designer drugs Manufactured or synthetic drugs designed to resemble already existing illegal psychoactive drugs and to produce or mimic their psychoactive effects.

developmental norms The average ages at which children perform various skills or exhibit particular abilities or behaviors.

developmental psychologists Psychologists who study a person's biological, emotional, cognitive, personal, and social development across the life span, from infancy through late adulthood.

developmental psychology The study of moral, social, emotional, and cognitive development throughout a person's entire life.

***Diagnostic and Statistical Manual of Mental Disorders*-IV-Text Revision (DSM-IV-TR)** The 2000 edition of the American Psychiatric Association's uniform diagnostic system for assessing specific symptoms and matching them to almost 300 different mental disorders. The DSM-IV-TR has five major dimensions, or axes.

dialectical behavior therapy A type of cognitive-behavioral therapy that helps patients identify thoughts, beliefs, and assumptions that make their lives challenging and teaches them different ways to think and react.

diathesis stress theory of schizophrenia The idea that some people have a genetic predisposition (a diathesis) that interacts with life stressors to result in the onset and development of schizophrenia.

dichromats People who have trouble distinguishing red from green because their eyes have just two kinds of cones. This is an inherited condition, found most often in males, that results in seeing mostly shades of green, but it differs in severity.

diffusion of responsibility theory The idea that, in the presence of others, individuals feel less personal responsibility and are less likely to take action in a situation where help is required.

direction of a sound The brain determines the direction of a sound by calculating the slight difference in time that it takes sound waves to reach the two ears, which are about 6 inches apart.

discrimination In classical conditioning, the tendency for some stimuli but not others to elicit a conditioned response. In operant conditioning, the tendency for a response to be emitted in the presence of a stimulus that is reinforced but not in the presence of unreinforced stimuli. In social psychology, specific unfair behaviors exhibited toward members of a group.

discriminative stimulus In conditioning, a cue that behavior will be enforced.

disgust A universal facial expression—closing the eyes, narrowing the nostrils, curling the lips downward, and sometimes sticking out the tongue—that indicates the rejection of something unpleasant or offensive.

disorganized schizophrenia A subcategory of schizophrenia marked by bizarre ideas, often about one's body (bones melting), confused speech, childish behavior (giggling for no apparent reason, making faces at people), great emotional swings (fits of laughing or crying), and often extreme neglect of personal appearance and hygiene.

displacement Transferring feelings from their true source to another source that is safer and more socially acceptable.

display rules Specific cultural norms that regulate when, where, and how much emotion we should or should not express in different situations.

dispositional attributions *See* internal attributions.

dissociative amnesia A dissociative disorder characterized by the inability to recall important personal information or events and usually associated with stressful or traumatic events. The importance of the information forgotten or the duration of the memory lapse is too great to be explained by normal forgetfulness.

dissociative disorder A disorder characterized by a disruption, split, or breakdown in a person's normally integrated and functioning consciousness, memory, sense of identity, or perception.

dissociative fugue A disturbance in which an individual suddenly and unexpectedly travels away from home or place of work and is unable to recall his or her past. The person may not remember his or her identity or may be confused about his or her new, assumed identity.

dissociative identity disorder The presence in a single individual of two or more distinct identities or personality states, each with its own pattern of perceiving, thinking about, and relating to the world. Different personality states may take control of the individual's thoughts and behaviors at different times. Formerly called multiple personality disorder.

distinctiveness In making attributions, determining how differently the person behaves in one situation in comparison with other situations.

divergent thinking Beginning with a problem and coming up with many different solutions.

dominant gene A type of polymorphic gene that determines the development of a specific trait even if it is paired with a recessive gene.

dopamine theory The idea that, in schizophrenia, the dopamine neurotransmitter system is somehow overactive and gives rise to a wide range of symptoms.

double-blind procedure An experimental design in which neither the researchers nor the subjects know which group is receiving which treatment. This design makes it possible to separate the effects of medical treatment from the participants' beliefs or expectations about the treatment.

double standard for sexual behavior A set of beliefs, values, and expectations that subtly encourages sexual activity in men but discourages the same behavior in women.

Down syndrome A genetic disorder that results from an extra 21st chromosome and causes abnormal physical traits (a fold of skin at the corner of each eye, a wide tongue, heart defects) and abnormal brain development, resulting in degrees of mental retardation.

dream interpretation A Freudian technique of dream analysis, based on the assumption that dreams contain underlying, hidden meanings and symbols that provide clues to unconscious thoughts and desires. Freud distinguished between a dream's manifest content—the plot of the dream at the surface level—and its latent content—the hidden or disguised meaning of the plot's events.

dreaming A unique state of consciousness in which we are asleep but we experience a variety of images, often in color. People blind from birth have only auditory or tactile dreams, while sighted people have dreams with astonishing visual, auditory, and tactile images.

DSM-IV-TR *See Diagnostic and Statistical Manual of Mental Disorders*-IV-Text Revision.

dyslexia An unexpected difficulty learning to read despite intelligence, motivation, and education. Causes of dyslexia include genetic factors (defects in neural circuitry) and environmental factors (disadvantaged schooling).

dysthymic disorder A mood disorder characterized by feeling chronically but not continuously depressed for a period of two years. While depressed, a person experiences at least two of the following symptoms: poor appetite, insomnia, fatigue, low self-esteem, poor concentration, and feelings of hopelessness.

E

eardrum *See* tympanic membrane.

echoic memory A form of sensory memory that holds auditory information for 1–2 seconds.

eclectic approach An approach to therapy in which the psychotherapist combines techniques and ideas from many different schools of thought.

ecstasy *See* MDMA.

ECT *See* electroconvulsive therapy.

EEG Electroencephalography—a procedure that involves placing electrodes at various points across a person's scalp. The electrodes detect brain wave activity throughout the brain's surface.

efferent neurons Neurons that carry information away from the spinal cord to produce responses in various muscles and organs throughout the body. Also called motor neurons.

effortful encoding The transfer of information from short-term into long-term memory either by working hard to repeat or rehearse the information or by making associations between new and old information.

ego Freud's second division of the mind, which develops from the id during infancy; its goal is to find safe and socially acceptable ways of satisfying the id's desires and to negotiate between the id's wants and the superego's prohibitions.

egocentric thinking Seeing and thinking of the world only from your own viewpoint and having difficulty appreciating someone else's viewpoint.

elaborative rehearsal Making meaningful associations between information to be learned and information already learned. An effective strategy for encoding information into long-term memory.

Electra complex *See* Oedipus complex.

electroconvulsive therapy (ECT) A treatment for depression in which electrodes are placed on the skull and a mild electric current is administered. As it passes through the brain, the current causes a seizure. Usual treatment consists of 10 to 12 ECT sessions, at the rate of about three per week.

embryonic stage The second stage of the prenatal period, spanning the 2–8 weeks that follow conception; during this stage, cells divide and begin to differentiate into bone, muscle, and body organs.

EMDR *See* Eye Movement Desensitization and Reprocessing.

emotion A response consisting of four components: interpreting or appraising a stimulus (event, object, or thought) in terms of one's well-being; having a subjective feeling, such as happiness or sadness; experiencing physiological responses, such as changes in heart rate or breathing; and possibly showing overt behaviors, such as smiling or crying.

emotion-focused coping Making some effort to deal with the emotional distress caused by a harm/loss or threat appraisal. These efforts include seeking support and sympathy, avoiding or denying the situation, and redirecting our attention.

emotional development The process in which genetic factors, brain changes, cognitive factors, coping abilities, and cultural factors influence and interact in the development of emotional behaviors, expressions, thoughts, and feelings.

emotional intelligence The ability to perceive and express emotion, understand and reason with emotion, and regulate emotion in oneself and others.

encoding Placing or storing information—such as images, events, or sounds (music, noise, speech)—in memory by making mental representations.

end bulbs Bulblike swellings at the extreme ends of axons' branches that store chemicals called neurotransmitters, which are used to communicate with neighboring cells.

endocrine system Numerous glands, located throughout the body, that secrete various chemicals called hormones, which affect organs, muscles, and other glands in the body.

endorphins Chemicals produced by the brain and secreted in response to injury or severe physical or psychological stress. Their powerful pain-reducing properties are similar to those of morphine.

environmental factors Our social, political, and cultural influences as well as our particular learning experiences.

environmental language factors Interactions that children have with parents, peers, teachers, and others whose feedback rewards and encourages language development; these interactions also provide opportunities for children to observe, imitate, and practice language skills.

episodic memory A type of declarative memory, consisting of knowledge about one's personal experiences (episodes) or activities, such as naming or describing favorite restaurants, movies, songs, habits, or hobbies.

ESP *See* extrasensory perception.

estrogen One of the major female hormones. At puberty, estrogen levels increase eightfold and stimulate the development of both primary and secondary sexual characteristics.

ethologists Behavioral biologists who observe and study animal behavior in the animal's natural environment or under relatively naturalistic conditions.

evening persons People who prefer to get up late, go to bed late, and engage in afternoon or evening activities. *See* morning persons.

event schemas Social schemas containing behaviors that we associate with familiar activities, events, or procedures. Also called scripts.

evolution *See* theory of evolution.

evolutionary approach A psychological viewpoint that focuses on how evolutionary ideas, such as adaptation and natural selection, explain human behaviors and mental processes.

evolutionary theory of emotions The theory that says one function of emotions is to help a person evaluate objects, people, and situations in terms of how good or bad they are for the individual's well-being and survival.

evolutionary theory of gender differences The idea in sociobiology, which emphasizes genetic and biological forces, that current behavioral and cognitive differences between men and women can be traced back to different survival problems faced by early women and men and the different behaviors they adapted to survive.

exemplar model The idea that a person forms a concept of an object, event, animal, or person by defining or making a mental list of the essential characteristics of that particular thing.

exhaustion stage The third stage in the general adaptation syndrome. In reaction to long-term, continuous stress, there is actual breakdown in internal organs or weakening of the infection-fighting immune system.

experiment A method for identifying cause-and-effect relationships by following a set of rules and guidelines that minimize the possibility of error, bias, and chance occurrences. *See also* laboratory experiment.

experimental group In an experiment, the subjects who receive the treatment.

experimental psychology The study of sensation, perception, learning, human performance, motivation, and emotion in carefully controlled laboratory conditions, with both animal and human subjects.

exposure therapy A treatment for anxiety in which the person is gradually exposed to the real anxiety-producing situations or objects that he or she is attempting to avoid; exposure treatment is continued until the anxiety decreases.

extensions of waking life theory of dreams The theory that our dreams reflect the same thoughts, fears, concerns, problems, and emotions that we have when awake.

external attributions Explanations of behavior based on the external circumstances or situations. Also called situational attributions.

external ear An oval-shaped structure that protrudes from the side of the head. Its function is to pick up sound waves and send them along the auditory canal.

extinction In classical conditioning, the reduction in a response when the conditioned stimulus is no longer followed by the unconditioned stimulus. As a result, the conditioned stimulus tends to no longer elicit the conditioned response. In operant conditioning, the reduction in the operant response when it is no longer followed by the reinforcer.

extrasensory perception (ESP) A group of psychic experiences that involve perceiving or sending information (images) outside normal sensory processes or channels. ESP includes four general abilities: telepathy, precognition, clairvoyance, and psychokinesis.

extrinsic motivation Engaging in certain activities or behaviors that either reduce our biological needs or help us obtain incentives or external rewards.

Eye Movement Desensitization and Reprocessing (EMDR) A new technique in which the client focuses on a traumatic memory while visually following the back-and-forth movement of a therapist's hand or pen. The process usually continues for several 90-minute sessions, after which the traumatic memories are greatly reduced or eliminated.

eyewitness testimony Recollection or recognition of a suspect observed during a possibly disruptive emotional situation that may have interfered with accurate remembering.

F

facial expressions Social signals that accompany emotions and express the state of our personal feelings; they provide social signals that elicit a variety of responses from those around us.

facial feedback theory The idea that sensations or feedback from the movement of facial muscles and skin are interpreted by your brain as emotional feelings.

factor analysis A complicated statistical method that finds relationships among different or diverse items and allows them to be grouped together.

farsightedness A visual acuity problem that may result when the eyeball is too short, so that objects are focused at a point slightly behind the retina. The result is that distant objects are clear, but near objects are blurry.

FAS *See* fetal alcohol syndrome.

fat cells Cells that store body fat. The number of fat cells in the body is primarily determined by heredity. They do not normally multiply except when we become obese. Fat cells shrink as we give up fat and lose weight and greatly enlarge as we store fat and gain weight.

fear of failure A tendency to avoid failure by choosing easy, nonchallenging tasks where failure is unlikely or difficult.

female hypothalamus Because of neural programming in the womb, the hypothalamus, a structure in the brain that controls the endocrine system, functions differently in the male and female. The female hypothalamus triggers a cyclical release of estrogens from the ovaries. The increased estrogen level is responsible for female secondary sexual characteristics, such as pubic hair, breast development, and widening of the hips. The cyclic release of hormones (estrogen and progesterone) also regulates the menstrual cycle.

female secondary sexual characteristics Sexual characteristics whose development in the female is triggered by the increased secretion of estrogen during puberty; they include the growth of pubic hair, development of breasts, and widening of hips.

fertilization *See* conception.

fetal alcohol syndrome (FAS) A condition caused by heavy drinking by the mother during pregnancy. It results in a combination of physical changes, such as short stature, flattened nose, and short eye openings, and psychological defects, such as degrees of mental retardation and hyperactivity.

fetal stage The third stage in prenatal development, beginning two months after conception and lasting until birth.

fight-flight response A state of increased physiological arousal that (1) directs great resources of energy to the muscles and brain; (2) can be triggered by either physical stimuli that threaten our survival or psychological situations that are novel, threatening, or challenging; and (3) involves numerous physiological responses that arouse and prepare the body for action—fight or flight. Caused by the activation of the sympathetic nervous system, it helps us to cope with, and survive, threatening situations.

figure-ground rule A perceptual rule stating that, in organizing stimuli, we tend to automatically distinguish between a figure and a ground: The figure, with more detail, stands out against the background, which has less detail.

five-factor model An approach to personality in which all traits are organized into five categories—openness, conscientiousness, extraversion, agreeableness, and neuroticism—that are used to describe differences in personality.

fixation A Freudian process through which an individual may be locked into any one of the three psychosexual stages—oral, anal, or phallic—because his or her wishes were either overgratified or undergratified in that stage.

fixed action pattern An innate biological force that predisposes an organism to behave in a fixed way in the presence of a specific environmental condition. Previously called instinct.

fixed-interval schedule In conditioning, a schedule in which a reinforcer occurs following a subject's first response after a fixed interval of time.

fixed-ratio schedule In conditioning, a schedule in which a reinforcer occurs only after a fixed number of responses by the subject.

flashbulb memories Vivid recollections, usually in great deal, of dramatic or emotionally charged incidents, which are encoded effortlessly and may last for long periods of time.

flavor What we experience when we combine the sensations of taste and smell.

fMRI *See* functional magnetic resonance imaging.

food-entrainable circadian clock A sort of timing device that regulates eating patterns in people and animals and might be responsible for late-night eating in people.

foot-in-the-door technique A method of persuasion that relies on the increased probability of compliance to a second request if a person complies with a small first request.

forebrain The largest part of the brain, consisting of left and right hemispheres connected by a wide band of fibers, the corpus callosum. The hemispheres are responsible for a vast array of responses, including learning and memory, speaking and language, emotional responses, experiencing sensations, initiating voluntary movements, planning, and making decisions.

forgetting Inability to retrieve, recall, or recognize information that was stored or is still stored in long-term memory.

forgetting curve A graph measuring the amount of previously learned information that subjects can recall or recognize across time.

formal operations stage Piaget's fourth cognitive stage, lasting from about 12 years of age through adulthood. During this stage, adolescents and adults develop the ability to think about abstract or hypothetical concepts, to consider an issue from another person's viewpoint, and to solve cognitive problems in a logical manner.

fragile X syndrome A defect in the X chromosome that can result in physical changes such as a relatively large head with protruding ears and mild to profound mental retardation.

fraternal twins Twins who develop from separate eggs and share 50% of their genes.

free association A Freudian technique in which clients are encouraged to talk about any thoughts or images that enter their heads; the assumption is that this kind of free-flowing, uncensored talking will provide clues to unconscious material.

frequency distribution The range of scores we get and the frequency of each one, when we measure a sample of people (or objects) regarding some trait.

frequency theory In pitch perception, the idea that, for low-frequency sound waves (1,000 cycles or less), the rate at which nerve impulses reach the brain determines how low a sound is. A rate of 50 impulses per second is interpreted as a lower sound than a rate of 200 impulses per second.

Freudian slips Mistakes or slips of the tongue that we make in everyday speech; such mistakes are thought to reflect unconscious thoughts or wishes.

Freud's psychodynamic theory of personality A personality theory that emphasizes the importance of early childhood experiences, repressed thoughts that we cannot voluntarily access, and the conflicts between conscious and unconscious forces that influence our thoughts and behaviors. *See also* psychoanalytic approach.

Freud's theory of dreams A theory that says we have a "censor" that protects us from realizing threatening and unconscious desires or wishes, especially those involving sex or aggression, by transforming them into harmless symbols that appear in our dreams and do not disturb our sleep or conscious thoughts.

Freud's theory of the unconscious The idea that, when faced with very threatening—especially sexual or aggressive—wishes or desires, we automatically defend our self-esteem by placing these psychologically dangerous thoughts into a mental place, the unconscious, that is sealed off from voluntary recall.

frontal lobe An area in the front part of the brain that includes a huge area of cortex. The frontal lobe is involved in many functions: performing voluntary motor movements, interpreting and performing emotional behaviors, behaving normally in social situations, maintaining a healthy personality, paying attention to things in the environment, making decisions, and carrying out plans.

frontal lobotomy A surgical procedure in which about one-third of the front part of the frontal lobe is separated from the rest of the brain.

frustration The feeling that results when our attempts to reach some goal are blocked.

frustration-aggression hypothesis The idea that, when our goals are blocked, we become frustrated and respond with anger and aggression. *See also* modified frustration-aggression hypothesis.

functional fixedness A mental set characterized by the inability to see an object as having a function different from its usual one.

functional magnetic resonance imaging (fMRI) A brain scan that measures the activity of specific neurons that are functioning during cognitive tasks such as thinking, listening, or reading.

functionalism An early school of psychological thought that emphasized the function rather than the structure of consciousness and was interested in how our minds adapt to our changing environment.

fundamental attribution error Our tendency, when we look for causes of a person's behavior, to focus on the person's disposition or personality traits and overlook how the situation influenced the person's behavior.

G

galvanic skin response Changes in sweating of the fingers (or palms) that accompany emotional experiences and are independent of perspiration under normal temperatures.

Ganzfeld procedure A controlled method for eliminating trickery, error, and bias while testing telepathic communication between two people.

Gardner's multiple-intelligence theory The idea that, instead of one kind of general intelligence, there are at least seven different kinds: verbal intelligence, musical intelligence, logical-mathematical intelligence, spatial intelligence, body movement intelligence, intelligence to understand oneself, and intelligence to understand others.

GAS *See* general adaptation syndrome.

gate control theory The idea that nonpainful nerve impulses compete with pain impulses as they enter the spinal cord, creating a neural gate through which only the nonpainful impulses pass; the pain impulses do not reach the brain. Thus, we can reduce feelings of pain by rubbing an injured area or becoming absorbed in other activities.

gender identity The individual's subjective experience and feelings of being either a male or a female; formerly called sexual identity.

gender identity disorder Commonly referred to as transsexualism, an individual's strong desire or feeling of wanting to be the opposite sex, discomfort with being one's assigned sex, and the wish to live as a member of the other sex.

gender roles Traditional or stereotypical behaviors, attitudes, and personality traits that parents, peers, and society designate as masculine or feminine. Gender roles affect how we think and behave; formerly called sex roles.

gender schemas Sets of information and rules organized around how either a male or a female should think and behave.

gene A specific segment on the strand of DNA (the chromosome) that contains instructions for making proteins, the chemical building blocks from which all the parts of the brain and body are constructed.

general adaptation syndrome (GAS) According to Selye, a series of three stages—alarm, resistance, and exhaustion—that correspond to the three different reactions of the body to stressful situations and that gradually increase the chances of developing psychosomatic symptoms.

generalization In classical conditioning, the tendency for a stimulus that is similar to the original conditioned stimulus to elicit a response that is similar to the conditioned response. Usually, the more similar the new stimulus is to the original conditioned stimulus, the larger will be the conditioned response. In operant conditioning, the situation in which an animal or a person emits the same response to similar stimuli.

generalized anxiety disorder A psychological disorder primarily characterized by excessive and/or unrealistic worry or feelings of general apprehension about events or activities. These anxious feelings occur on a majority of days for a period of at least six months.

genetic factors in mental disorders Unlearned or inherited tendencies that influence how a person thinks, behaves, and feels.

genetic hunger factors Inherited instructions found in our genes that influence our hunger; these instructions may determine our number of fat cells or our metabolic rate of burning off the body's fuel, for example, and push us toward being normal, overweight, or underweight.

genetic marker An identifiable gene or number of genes or a specific segment of a chromosome that is directly linked to some behavioral, physiological, or neurological trait or disease.

genetic mutation An accidental error in genetic instructions that leads to a change in an organism.

genetic sex factors Inherited instructions for the development of sexual organs, the secretion of sex hormones, and the wiring of the neural circuits that control sexual reflexes.

genetic testing A procedure that involves taking a sample from someone's blood, hair, skin, or other body parts and then examining the person's genes to look for signs that the person may be at risk for specific diseases or disorders.

genital cutting The practice of cutting away the female's external genitalia, usually including her clitoris and surrounding skin (labia minora). The remaining edges are sewn together, which leaves only a small opening for urination and menstruation.

genital stage Freud's fifth, and final, psychosexual stage, lasting from puberty through adulthood. In this stage, the individual has renewed sexual desires that he or she seeks to fulfill through relationships with other people.

germinal stage The first stage of prenatal development, lasting two weeks from the moment of conception.

Gestalt approach An older theoretical approach that emphasized the idea that perception is more than the sum of its parts. In contrast to the structuralists, the Gestalt psychologists believed that perceptions are formed by the brain on the basis of a set of rules that specify how individual elements may be organized to form a meaningful pattern—that is, a perception.

gifted A term applied to an individual (usually a child) who has above-average intelligence as well as some superior talent or skill. A moderately gifted child is usually defined by an IQ score between 130 and 150; a profoundly gifted child has an IQ score of 180 or above.

glial cells Cells in the nervous system that have at least three functions: They provide scaffolding to guide the growth of developing neurons and support mature neurons; they wrap themselves around neurons and form a kind of insulation to prevent interference from other electrical signals; and they release chemicals that influence a neuron's growth and function.

gonads Glands—the ovaries in females and the testes in males—that produce hormones to regulate sexual development, ovulation or sperm production, and the growth of sex organs. They are part of the endocrine system.

grammar A set of rules for combining words into phrases and sentences to express an infinite number of thoughts that can be understood by others.

group A collection of two or more people who interact and share some common attribute or purpose. A group also influences how its members think and behave.

group cohesion Group togetherness, which is determined by how much group members perceive that they share common attributes.

group norms Formal or informal rules about how group members should behave.

group polarization The phenomenon in which group discussion reinforces the majority's point of view and shifts that view to a more extreme position.

groupthink Poor group decision making that occurs when group discussions emphasize cohesion and agreement rather than critical thinking and the best possible outcome.

growth needs According to Maslow, higher-level needs that are not essential to existence, such as the desire for truth, goodness, beauty, and justice.

H

hair cells The auditory receptors. These miniature hair-shaped cells rise from the basilar membrane in the cochlea.

hallucinations Sensory experiences without any stimulation from the environment. Common symptoms of schizophrenia, hallucinations may be auditory, such as hearing voices, or may include distorted perceptions, such as feeling that parts of one's body are too small or too large.

hallucinogens Psychoactive drugs that can produce hallucinations—strange perceptual, sensory, and cognitive experiences that the person sees or hears but knows are not occurring in reality. Such unreal experiences are called hallucinations.

happiness A mental state that includes three components: feeling positive emotions, being satisfied with one's life, and not experiencing negative emotions.

hardiness A combination of three personality traits—control, commitment, and challenge—that protect or buffer us from the potentially harmful effects of stressful situations and reduce our chances of developing psychosomatic illness.

harm/loss appraisal Our conclusion that we have already sustained some damage or injury in a particular situation.

hassles Small, irritating, frustrating events that we face daily and that we usually appraise as stressful experiences.

hazing Part of a group's initiation ritual during which individuals are subjected to a variety of behaviors that range from humiliating and unpleasant to potentially dangerous both physically and psychologically.

helping *See* prosocial behavior.

heritability A statistical measure that estimates the amount or proportion of some ability, characteristic, or trait that can be attributed to genetic factors.

heterosexual orientation A pattern of sexual arousal by persons of the opposite sex.

heuristics Rules of thumb that reduce the number of operations or allow us to take shortcuts in solving problems.

hierarchy of needs *See* Maslow's hierarchy of needs.

high need for achievement A tendency to persist longer at tasks; show better performance on tasks, activities, or exams; set challenging but realistic goals; compete with others to win; and be attracted to careers that require initiative.

hindbrain An area at the base of the brain that is involved in sleeping, waking, coordinating body movements, and regulating vital reflexes (heart rate, blood pressure, and respiration).

hippocampus A curved structure within the temporal lobe that is involved in transforming many kinds of fleeting memories into permanent storage. It forms part of the limbic system.

histrionic personality disorder A disorder characterized by excessive emotionality and attention seeking. It is found in 2% of the population.

HIV positive Having HIV antibodies, which implies infection by the human immunodeficiency virus (HIV).

holistic view The idea, emphasized in humanistic theories, that a person's personality is more than the sum of its individual parts; instead, the individual parts form a unique and total entity that functions as a unit.

homeostasis The tendency of the sympathetic and parasympathetic divisions of the autonomic nervous system to work together to maintain the body's level of arousal in balance for optimum functioning.

homosexual orientation A pattern of sexual arousal by persons of the same sex.

humanistic approach A psychological viewpoint emphasizing that each individual has great freedom in directing his or her future, considerable capacity for achieving personal growth, intrinsic worth, and enormous potential for self-fulfillment.

humanistic theories *See* humanistic approach.

hypnosis A situation or set of procedures in which a researcher, clinician, or hypnotist suggests to another person that he or she will experience various changes in sensation, perception, cognition, or control over motor behaviors.

hypnotic analgesia Reduction in pain reported by clients after undergoing hypnosis and receiving suggestions that reduced anxiety and promoted relaxation.

hypnotic induction Various methods of inducing hypnosis, such as asking subjects to close their eyes and go to sleep, having them fix their attention on an object (for example, a watch), and instructing them to go into deep relaxation.

hypothalamus A structure of the limbic system that is located near the bottom middle of the brain and regulates many motivational and emotional behaviors. It controls much of the endocrine system by regulating the pituitary gland.

hypothesis An educated guess about some phenomenon, stated in precise, concrete language so as to rule out any confusion or error in the meaning of its terms.

I

iconic memory A form of sensory memory that holds visual information for about a quarter of a second or longer. (The word *icon* means "image.")

id Freud's first division of the mind, which contains two biological drives—sex and aggression—that are the source of all psychic or mental energy. The id's goal is to pursue pleasure and satisfy the biological drives.

ideal self According to Rogers, the self that is based on our hopes and wishes and reflects how we would like to see ourselves; its complement is the real self.

ideal weight *See* optimal weight.

identical twins Twins who develop from a single egg and thus have almost exactly the same genes.

identity How we describe ourselves, including our values, goals, traits, interests, and motivations.

illusion Perception of an image so distorted that, in reality, it cannot and does not exist. An illusion is created when space, size, and depth cues are manipulated so that our brains can no longer correctly interpret them.

imaginary audience Adolescents' belief that everyone is watching all of their actions.

imagined perception In hypnosis, the subject's willingness, at the hypnotist's suggestion, to respond to nonexistent stimuli and imaginary perceptions. It can also include bizarre behaviors, such as imitating Elvis Presley in public.

immune system The body's defense and surveillance network of cells and chemicals that fight off bacteria, viruses, and other foreign or toxic substances.

implicit or nondeclarative memory Mental and emotional processes that we are unaware of but that bias and influence our conscious feelings, thoughts, and behaviors. *See* procedural memory.

impossible figure A perceptual experience in which a drawing seems to defy basic geometric laws.

imprinting Inherited tendencies or responses that newborn animals display when they encounter certain stimuli in their environment.

incentives Environmental factors, such as external stimuli, reinforcers, or rewards, that motivate our behavior.

independent variable In an experiment, a treatment or something else that the researcher controls or manipulates.

industrial/organizational psychology The study of people and their relationships with their work environments.

inferential statistics A set of procedures for determining what conclusions can be legitimately inferred from a set of data.

informational influence theory The theory that we use the reactions of others to judge the seriousness of the situation.

inhibited/fearful children Kagan's term for children who show reluctance, anxiety, or fear (measured by motor activity, fretting, or crying) when approaching a strange child, exploring novel objects, playing with a peer, or talking to an unfamiliar adult. In addition, inhibited children show increased physiological arousal to novel or strange situations.

inhibited female orgasm A persistent delay or absence of orgasm after becoming aroused and excited.

innate language factors Genetically programmed physiological and neurological features of the brain and vocal apparatus that facilitate our making speech sounds and learning language skills.

insanity According to the legal definition, not knowing the difference between right and wrong.

insecure attachment An emotional bond characteristic of infants who avoid, or show ambivalence toward, their parents.

insight A mental process marked by the sudden and unexpected solution to a problem; a phenomenon often called the "ah-ha!" experience.

insight therapy An approach in which the therapist and client talk about the client's symptoms and problems, with the goal of identifying the cause of the problem. Once the client has an insight into the cause of the problem, possible solutions can be discussed with the therapist.

insomnia Difficulties in going to sleep or in staying asleep through the night. Associated daytime complaints include fatigue, impairment of concentration, memory difficulty, and lack of well-being. About 33% of adult Americans report some type of insomnia.

instincts According to McDougall (1908), innate tendencies or biological forces that determine behavior; now used as a synonym for fixed action pattern.

intelligence quotient (IQ) A measure of intelligence computed by dividing a child's mental age, as measured in an intelligence test, by the child's chronological age and multiplying the result by 100.

interactive model of sexual orientation The theory that genetic and biological factors, such as genetic instructions and prenatal hormones, interact with psychological factors, such as the individual's attitudes, personality traits, and behaviors, to influence the development of sexual orientation.

interference The forgetting process in which the recall of some particular memory is blocked or prevented by new information that overwrites or interferes with it. *See also* proactive interference and retroactive interference.

internal attributions Explanations of behavior on the basis of the internal characteristics (or dispositions) of the person performing the behavior. Also called dispositional attributions.

interneuron A relatively short neuron whose primary task is to make connections between other neurons.

interposition In three-dimensional vision, a monocular depth cue that comes into play when objects overlap. The overlapping object appears closer, and the object that is overlapped appears to be farther away.

interval timing clock A sort of timing device, located in the basal ganglia of the brain, that gauges the passage of seconds, minutes, or hours and helps creatures know when to start or stop doing some activity.

intervention program A program for disadvantaged children that creates an environment offering increased opportunities for intellectual, social, and personality-emotional development while ensuring good physical health.

interview A technique for obtaining information by asking questions, ranging from open-ended to highly structured, about a subject's behaviors and attitudes, usually in a one-on-one situation.

intestines The body organ that responds to the presence of food, especially fats, by secreting a hormone called CCK (cholecystokinin), which inhibits eating.

intimacy In Sternberg's triangular theory of love, the component of love associated with feeling close and connected to someone; it develops through sharing and communicating.

intrinsic motivation Engaging in certain activities or behaviors because they are personally rewarding or because we are fulfilling our beliefs or expectations.

introspection A method of exploring conscious mental processes adopted by the structuralists; subjects were asked to look inward and report their sensations and perceptions.

intrusive thoughts Thoughts that we repeatedly experience, that are usually unwanted or disruptive, and that are very difficult to stop or eliminate.

ions Electrically charged chemical particles, which obey the rule that opposite charges attract and like charges repel.

IQ *See* intelligence quotient.

iris A circular muscle that surrounds the pupil and controls the amount of light that enters the eye. In dim light, the iris relaxes, allowing more light to enter—the pupil dilates; in bright light, the iris constricts, allowing less light to enter—the pupil constricts. The iris muscle contains the pigment that gives the eye its characteristic color.

J

James-Lange theory The idea that our brains interpret specific physiological changes as feelings or emotions and that there is a different physiological pattern underlying each emotion.

jet lag A condition in which travelers' internal circadian rhythm is out of step, or synchrony, with the external clock time at their new location. They experience fatigue, disorientation, lack of concentration, and reduced cognitive skills. It takes about one day to reset the circadian clock for each hour of time change.

just noticeable difference (JND) The smallest increase or decrease in the intensity of a stimulus that a person can manage to detect.

L

labeling A process of identifying differences among individuals and placing them into specific categories, which may have either positive or negative associations.

laboratory experiment A technique to gather information by studying behavior in a controlled environment that permits the careful manipulation of some treatment and the measurement of the treatment's effects on behavior.

laboratory setting An environment in which individuals may be studied under systematic and controlled conditions, thus eliminating many real-world influences.

language A form of communication in which we learn and use complex rules to form and manipulate symbols (words or gestures) that are used to generate an endless number of meaningful sentences.

language stages Four different periods in a child's acquisition of language and grammar: babbling, single words, two-word combinations, and sentences. In each subsequent stage, a child displays new and more complex language skills.

latency stage The fourth of Freud's psychosexual stages, lasting from the age of about 6 years to puberty. In this stage, the child represses sexual thoughts and engages in nonsexual activities, such as developing social and intellectual skills.

lateral hypothalamus A group of brain cells that regulates hunger by creating feelings of being hungry.

law of effect The principle that behaviors followed by positive (pleasurable) consequences are strengthened (and thus will likely occur in the future), while behaviors followed by negative consequences are weakened.

learning A relatively permanent change in behavior (both unobservable mental events and observable responses) associated with specific stimuli and/or responses that change as a result of experience.

learning–performance distinction The idea that learning may occur but may not always be measured by, or immediately evident in, performance.

lens A transparent, oval structure in the eye whose curved surface functions to bend and focus light waves into an even narrower beam. The lens is attached to muscles that adjust the curve of the lens, which, in turn, adjusts the focusing.

levels-of-processing theory The theory that memory depends on how well information is encoded in the mind. Information is encoded at a shallow level if we simply pay attention to its basic features but is encoded at a deep level if we form new associations with existing information. According to the theory, poor memory corresponds to information encoded at a shallow level, and good memory to information encoded at deep levels.

lie detector tests *See* polygraph tests.

light and shadow A monocular depth cue; brightly lit objects appear closer, while objects in shadows appear farther away.

light therapy The use of bright, artificial light to reset circadian rhythms and so combat the insomnia and drowsiness that plague shift workers and jet-lag sufferers; it is also used to help people with sleeping disorders in which the body fails to stay in time with the external environment.

limbic system A group of about half a dozen interconnected structures in the core of the forebrain that are involved in many motivational behaviors, such as obtaining food, drink, and sex; organizing emotional behaviors such as fear, anger, and aggression; and storing memories. It is sometimes referred to as our primitive, or animal, brain because the same structures are found in the brains of animals that are evolutionarily very old.

linear perspective In three-dimensional vision, a monocular depth cue associated with the convergence of parallel lines in the far distance.

linguistic relativity *See* theory of linguistic relativity.

liver The body organ that monitors nutrients, especially the level of glucose (sugar) in the blood. When the level of glucose falls, the liver signals hunger; when the level of glucose rises, the liver signals fullness.

lobes The four areas into which the brain's cortex is divided.

locus of control Our beliefs concerning how much control we have over situations or rewards. For each of us, these beliefs lie somewhere on a continuum between internal and external locus of control. We have an internal locus of control if we believe that we have control over situations and rewards and an external locus of control if we believe that we do not have control over situations and rewards and that events outside ourselves (fate) determine what happens.

long-term memory The process that can store almost unlimited amounts of information over long periods of time.

long-term potentiation (LTP) The increased sensitivity of a neuron to stimulation after it has been repeatedly stimulated. Neuroscientists believe that the LTP process may be the basis for learning and memory in animals and humans.

longitudinal method A research design in which the same group of individuals is studied repeatedly at many different points in time.

loudness Our subjective experience of a sound's intensity, which is determined by the height (amplitude) of the sound wave. The brain calculates loudness from the rate of nerve impulses that arrive in the auditory nerve.

LSD (*d*-lysergic acid diethylamide) A very potent hallucinogen. Very small doses can produce experiences such as visual hallucinations, perceptual distortions, increased sensory awareness, and emotional responses that may last 8–10 hours.

LTP *See* long-term potentiation.

M

magnetic resonance imaging (MRI) A technique for studying the structure of the living brain. Nonharmful radio frequencies are passed through the brain, and a computer measures their interaction with brain cells and transforms this interaction into an incredibly detailed image of the brain (or body).

maintenance rehearsal The practice of intentionally repeating or rehearsing information (rather than forming any new associations) so that it remains longer in short-term memory.

major depressive disorder A mood disorder marked by at least two weeks of continually being in a bad mood, having no interest in anything, and getting no pleasure from activities. In addition, a person must have at least four of the following symptoms: problems with eating, sleeping, thinking, concentrating, or making decisions; lacking energy; thinking about suicide; and feeling worthless or guilty. Also called unipolar depression.

major life events Potentially disturbing, troubling, or disruptive situations, both positive and negative, that we appraise as having a significant impact on our lives.

maladaptive behavior approach In defining abnormality, the idea that a behavior is psychologically damaging or abnormal if it interferes with the individual's ability to function in one's personal life or in society.

maladaptive genes Genes for traits that prevent survival and reproduction. They are not selected in the process of evolution and consequently are eliminated in a species.

male hypothalamus Because of neural programming in the womb, the hypothalamus, a structure in the brain that controls the endocrine system, functions differently in the male and female. The male hypothalamus triggers a continuous release of androgens, such as testosterone, from the testes. The increased androgen level is responsible for male secondary sexual characteristics, such as facial and pubic hair, muscle growth, and lowered voice.

male secondary sexual characteristics Sexual characteristics whose development in the male is triggered by the increased secretion of testosterone during puberty; they include the growth of pubic hair, muscle development, and a change (deepening) of the voice.

marijuana A psychoactive drug whose primary active ingredient is THC (tetrahydrocannabinol), which is found in the leaves of the cannabis plant. Low doses produce mild euphoria; moderate doses produce perceptual and time distortions; and high doses may produce hallucinations, delusions, and distortions of body image.

Maslow's hierarchy of needs An ascending order, or hierarchy, in which biological needs are placed at the bottom and social needs at the top. As needs at lower levels are met, we advance to the next higher level. This hierarchy indicates that we satisfy our biological needs before we satisfy our social needs.

mass hysteria A condition experienced by a group of people who, through suggestion, observation, or other psychological processes, develop similar fears, delusions, abnormal behaviors, and, in some cases, physical symptoms.

maturation The succession of developmental changes that are genetically or biologically programmed rather than acquired through learning or life experiences.

MDMA Also called ecstasy, this drug resembles both mescaline (a hallucinogen) and amphetamine (a stimulant). It heightens sensations, gives a euphoric rush, raises body temperature, and creates feelings of warmth and empathy.

mean The arithmetic average of all the individual measurements in a distribution.

measure of variability An indication of how much scores in a distribution vary from one another.

median The score above and below which half the scores in the distribution fall.

medical therapy Any approach that uses psychoactive drugs, such as tranquilizers and neuroleptics, to treat mental disorders by changing biological factors, such as the levels of neurotransmitters in the brain.

medulla An area in the hindbrain, located at the top of the spinal cord, that includes a group of cells that control vital reflexes, such as respiration, heart rate, and blood pressure.

melatonin A hormone secreted by the pineal gland, an oval group of cells in the center of the human brain. Melatonin secretion, controlled by the suprachiasmatic nucleus, increases with darkness and decreases with light; thus, it plays a role in the regulation of circadian rhythms and in promoting sleep.

memory The ability to retain information over time through the processes of encoding, storing, and retrieving. Memories are not copies but representations of the world that vary in accuracy and are subject to error and bias.

menarche The first menstrual period; it is a signal that ovulation may have occurred and that the girl may have the potential to conceive and bear a child.

Meniere's disease Sudden attacks of dizziness, nausea, vomiting, and head-splitting buzzing sounds that result from a malfunction of the semicircular canals in the vestibular system.

menopause A gradual stoppage in the secretion of the major female hormone (estrogen). This process, which occurs in women at about age 50 (range 35–60), results in the cessation of ovulation and the menstrual cycle.

mental age The estimation of a child's intellectual progress, which is calculated by comparing the child's score on an intelligence test with the scores of average children of the same age.

mental disorder A prolonged or recurring problem that seriously interferes with an individual's ability to live a satisfying personal life and function adequately in society.

mental retardation Substantial limitation in present functioning, characterized by significantly subaverage intellectual functioning along with related limitations in two of ten areas, including communication, self-care, home living, social skills, and safety.

mescaline The active ingredient in the peyote cactus. At high doses, mescaline produces physiological arousal and very clear, colorful, and vivid visual hallucinations. It primarily increases the activity of the neurotransmitters norepinephrine and dopamine. Mescaline does not impair the intellect or cloud consciousness.

meta-analysis A powerful statistical procedure that compares the results of dozens or hundreds of studies to determine the effectiveness of some variable or treatment examined in those studies (for example, a type of therapy).

metabolic rate The efficiency with which the body breaks food down into energy and the speed with which the body burns off that fuel. An inherited trait, it can be raised by exercise or smoking.

methamphetamine (D-methamphetamine) A stimulant similar to amphetamine in both its chemical makeup and its physical and psychological effects. It causes marked increases in blood pressure and heart rate and feelings of enhanced mood, alertness, and energy. Methamphetamine, whose street names are meth, speed, crank, crystal, and ice, produces an almost instantaneous high when smoked and is highly addictive.

method of loci A mnemonic device, or encoding technique, that improves encoding by creating visual associations between memorized places and new items to be memorized.

midbrain The part of the brain that contains the reward/pleasure center, which is stimulated by food, sex, money, music, attractive faces, and some drugs (cocaine); contains areas for visual and auditory reflexes, such as automatically turning your head toward a noise; and holds the reticular formation, which arouses the forebrain so that it is ready to process information from the senses.

middle ear A bony cavity that is sealed at each end by a membrane. The two membranes are connected by three small bones, collectively called ossicles. Because of their shapes, these bones are referred to as the hammer, anvil, and stirrup. The ossicles act like levers that greatly amplify vibrations from the eardrum and transmit them to the oval window and inner ear.

mind-body connection The ability of our thoughts, beliefs, and emotions to produce physiological changes that may be either beneficial or detrimental to our health and well-being.

mind-body question The debate about how complex mental activities, such as feeling, thinking, learning, imagining, and dreaming, can be generated by the brain's physical membranes, fluids, and chemicals.

mind-body therapy An approach to healing based on the finding that thoughts and emotions can change physiological and immune responses. It attempts to increase physical and mental well-being by means of mental strategies, such as relaxation, meditation, and biofeedback, as well as social support groups.

Minnesota Multiphasic Personality Inventory-2-RF (MMPI-2) A true-false self-report questionnaire that consists of 567 statements describing a wide range of normal and abnormal behaviors. The purpose of MMPI-2 is to help distinguish normal from abnormal groups.

mnemonic methods Effective ways to improve encoding and create better retrieval cues by forming vivid associations or images that facilitate recall and decrease forgetting.

mode The most frequent measurement in a distribution.

modified frustration-aggression hypothesis The idea that although frustration may lead to aggression, a number of situational and cognitive factors may override the aggressive response.

monochromats Individuals who have total color blindness; their world looks like a black-and-white movie. This kind of color blindness is rare and results from individuals having only rods or only one kind of functioning cone instead of three.

monocular depth cues In three-dimensional vision, depth cues produced by signals from a single eye. They are most commonly determined by the way objects are arranged in the environment.

mood disorder A prolonged and disturbed emotional state that affects almost all of a person's thoughts and behaviors.

moral therapy The belief that mental patients could be helped to function better by receiving humane treatment in a relaxed and decent environment. This approach was fundamental to the reform movement of the early 1800s.

morning persons People who prefer to get up early, go to bed early, and engage in morning activities. *See* evening persons.

morphemes The smallest meaningful combination of sounds in a language.

morphology A system that we use to group phonemes—consonants and vowels—into meaningful combinations of sounds and words.

motion parallax In three-dimensional vision, a monocular depth cue based on the speed of moving objects: Objects that appear to be moving at high speed are interpreted as closer to us than those moving more slowly.

motion sickness Feelings of nausea and dizziness experienced in a moving vehicle when information from the vestibular system (that your head is bouncing around) conflicts with information reported by your eyes (that objects in the distance look fairly steady).

motivation Various physiological and psychological factors that cause us to act in a specific way at a particular time.

motor cortex A narrow strip of cortex that is located on the back edge of the frontal lobe and extends down its side. It is involved in the initiation of all voluntary movements. The right motor cortex controls muscles on the left side of the body, and vice versa.

motor development The stages of motor skills that all infants pass through as they acquire the muscular control necessary for making coordinated movements.

motor neurons *See* efferent neurons.

MRI *See* magnetic resonance imaging.

multiple-intelligence theory *See* Gardner's multiple-intelligence theory.

multiple sclerosis A disease that attacks the myelin sheaths that wrap around and insulate cells in the central nervous system. Because of this damage, messages between the brain and other parts of the body are disrupted, often causing problems in motor coordination, strength, and sensation.

myelin sheath A tubelike structure of fatty material that wraps around and insulates an axon, preventing interference from electrical signals generated in adjacent axons.

N

narcolepsy A relatively rare, chronic disorder marked by excessive sleepiness, usually in the form of sleep attacks or short periods of sleep throughout the day. The sleep attacks are accompanied by brief periods of REM sleep and loss of muscle control (cataplexy), which may be triggered by big emotional changes.

natural selection The process by which organisms that are better adapted to their environment tend to survive and produce more offspring, whereas those less adapted tend to be eliminated.

naturalistic setting A relatively normal environment in which researchers gather information by observing individuals' behaviors without attempting to change or control the situation.

nature-nurture question The debate concerning the relative contribution of genetic factors (nature) and environmental factors (nurture) to a person's intelligence as well as to his or her biological, emotional, cognitive, personal, and social development.

nearsightedness A visual acuity problem that may result when the eyeball is too long, so that objects are focused at a point slightly in front of the retina. The result is that near objects are clear, but distant objects appear blurry.

negative punishment Removal of a reinforcing stimulus (for example, taking away a child's allowance) after a response. This removal decreases the chances that the response will recur.

negative reinforcement The occurrence of an operant response that either stops or removes an aversive stimulus. Removal of the aversive stimulus increases the likelihood that the response will occur again.

negative symptoms of schizophrenia Symptoms that reflect a decrease in or loss of normal functions: decreased range and intensity of emotions, decreased ability to express thoughts, and decreased initiative to engage in goal-directed behaviors.

neglect syndrome The failure of a patient to see objects or parts of the body on the side opposite the brain damage when the damage is to an association area, usually in occipital and parietal lobes, and usually in the right hemisphere.

nerve impulse A series of separate action potentials that take place, segment by segment, as they move down the length of an axon.

nerves Stringlike bundles of axons and dendrites that are held together by connective tissue. Nerves in the peripheral nervous system have the ability to regrow, regenerate, or reattach if severed or damaged. They carry information from the senses, skin, muscles, and the body's organs to and from the spinal cord.

network hierarchy In the network theory of memory, the arrangement of nodes or categories so that concrete ideas are at the bottom of the hierarchy and are connected to more abstract ideas located above them. The most abstract ideas are at the top of the hierarchy.

network theory The theory that we store related ideas in separate memory categories, or files, called nodes. As we make associations between information, we create links among thousands of nodes, which make up a gigantic interconnected network for storing and retrieving information.

neural assemblies Groups of interconnected neurons whose activation allows information or stimuli to be recognized and held briefly and temporarily in short-term memory.

neural deafness Deafness caused by damage to the auditory receptors (hair cells), which prevents the triggering of impulses, or by damage to the auditory nerve, which prevents impulses from reaching the brain. *See also* cochlear implant.

neuroleptic drugs Drugs that change the levels of neurotransmitters in the brain. They are used to treat serious mental disorders, such as schizophrenia. Also called antipsychotic drugs.

neurons Cells that have specialized extensions for the reception and transmission of electrical signals.

neuroses According to Freud, maladaptive thoughts and actions that arise from some unconscious thought or conflict and indicate feelings of anxiety.

neurotransmitters About a dozen different chemicals that are made by neurons and then used for communication between neurons during the performance of mental or physical activities.

neutral stimulus A stimulus that causes a sensory response, such as being seen, heard, or smelled, but does not produce the reflex being tested.

nicotine A stimulant; it first produces arousal but then produces calming. Present in cigarettes, nicotine increases both heart rate and blood pressure. It improves attention and concentration, may improve short-term memory, but may interfere with complex processing. Regular use of nicotine causes addiction, and stopping leads to withdrawal symptoms.

night terrors Sleep disruptions in children that occur during stage 3 or stage 4 (delta) sleep. They usually start with a piercing scream, after which the child wakes suddenly in a fearful state, with rapid breathing and increased heart rate. The next morning, the child has no memory of the frightening experience.

nightmares Dreams that contain frightening and anxiety-producing images. They usually involve great danger—being attacked, injured, or pursued. Upon awakening, the dreamer can usually describe the nightmare in considerable detail. Nightmares occur during REM sleep.

nodes Memory files that contain related information organized around a specific topic or category.

non-REM sleep Stages 1–4 of sleep, in which rapid eye movement does not occur; it makes up about 80% of sleep time.

nonbenzodiazepines Drugs, such as Ambien and Sonata, that are popular sleeping pills because they act rapidly, are of short duration, and have few cognitive side effects.

noncompliance In children, refusal to follow directions, carry out a request, or obey a command given by a parent or caregiver. Noncompliance is one of the most common complaints of parents in general and the most frequent problem of parents who bring their children to clinics for treatment of behavioral problems.

nondeclarative memory *See* procedural memory.

nonintellectual factors Factors such as attitude, experience, and emotional functions that may help or hinder an individual's performance on intelligence tests.

normal aging A gradual and natural slowing of our physical and psychological processes from middle through late adulthood.

normal curve A graph of a frequency distribution in which the curve tapers off equally on either side of a central high point—in other words, a graph of a normal distribution.

normal distribution A bell-shaped frequency distribution curve. The scores are arranged symmetrically so that the vast majority fall in the middle range, with fewer scores near the two extreme ends of the curve.

O

obedience Behavior performed in response to an order given by someone in a position of authority.

obesity A body weight 30% or more above the ideal value.

object permanence The understanding that objects or events continue to exist even if they can no longer be heard, touched, or seen.

objective personality tests Tests consisting of specific written statements that require individuals to indicate—for example, by checking "true" or "false"—whether the statements do or do not apply to them; also called self-report questionnaires.

observational learning *See* social cognitive learning.

obsessive-compulsive disorder An anxiety disorder consisting of obsessions, which are persistent, recurring, irrational thoughts, impulses, or images that a person is unable to control and that interfere with normal functioning; and compulsions, which are irresistible impulses to perform over and over some senseless behavior or ritual (hand washing, checking things, counting, putting things in order).

obsessive-compulsive personality disorder A personality disorder characterized by an intense interest in being orderly, achieving perfection, and having control. It is found in 4% of the population.

occipital lobe A region at the very back of the brain that is involved in processing visual information, which includes seeing colors and perceiving and recognizing objects, animals, and people.

Oedipus complex According to Freud, a process in which a child competes with the parent of the same sex for the affections and pleasures of the parent of the opposite sex; called the Electra complex in girls.

olfaction The sense of smell. Its stimuli are various chemicals that are carried by the air.

olfactory cells The receptors for smell, located in the uppermost part of the nasal passages. As volatile molecules dissolve in the mucus covering the cells, they stimulate the receptors, which send nerve impulses to the brain.

operant conditioning A kind of learning in which the consequences—reward or punishment—that follow some behavior increase or decrease the likelihood of that behavior's occurrence in the future. Also called instrumental conditioning.

operant response A response that can be modified by its consequences. Operant responses offer a way of dividing ongoing behavior into meaningful and measurable units.

opiates Drugs derived from the opium poppy, including opium and morphine, which is chemically altered to make heroin. All opiates have three primary effects: analgesia (pain reduction); opiate euphoria, which is often described as a pleasurable state between waking and sleeping; and constipation. Continued use of opiates results in tolerance, physical addiction, and an intense craving for the drug.

opponent-process theory A theory of color vision suggesting that ganglion cells in the retina and cells in the thalamus respond to two pairs of colors: red-green and blue-yellow. When these cells are excited, they respond to one color of the pair; when inhibited, they respond to the complementary color.

optimal weight The body weight resulting from an almost perfect balance between how much food an organism eats and how much it needs to meet its body's energy needs; also called ideal weight.

optimism A relatively stable personality trait that leads one to believe and expect that good things will happen. It is one of the personality factors associated with lower stress levels and fewer chances of developing psychosomatic symptoms. *See* pessimism.

oral stage Freud's first psychosexual stage, which lasts for the first 18 months of life, in which the infant's pleasure seeking is centered on the mouth.

organic factors Medical conditions or drug or medication problems that lead to sexual difficulties.

organic retardation Mental retardation that results from genetic problems or brain damage.

ossicles *See* middle ear.

outer ear Three structures important to the hearing process: the external ear, auditory canal, and tympanic membrane (eardrum).

overgeneralization A common error during language acquisition, in which children apply a grammatical rule to cases where it should not be used.

overweight A body weight 20% over the ideal value.

ovulation The release of an ovum, or egg cell, from a woman's ovaries.

P

pain Sensations caused by various stimuli that activate the pain receptors, free nerve endings. Nerve impulses from these pain receptors travel to the somatosensory and limbic areas of the brain, where they are transformed into pain sensations. Pain is essential for survival: It warns us to avoid or escape dangerous situations or stimuli and makes us take time to recover from injury.

pancreas An organ that regulates the level of sugar in the bloodstream by secreting insulin. It forms part of the endocrine system.

panic attack A period of intense fear or discomfort in which four or more of the following symptoms are present: pounding heart, sweating, trembling, shortness of breath, feelings of choking, chest pain, nausea, feeling dizzy, and fear of losing control or dying.

panic disorder A mental disorder characterized primarily by recurrent and unexpected panic attacks, plus continued worry about having another attack; such worry interferes with psychological functioning.

paranoid personality disorder A pattern of distrust and suspiciousness and perceiving others as having evil motives. It is found in 0.5–2.5% of the population.

paranoid schizophrenia A subcategory of schizophrenia characterized by auditory hallucinations or delusions, such as thoughts of being persecuted by others or delusions of grandeur.

paraphilias Repetitive or preferred sexual fantasies involving nonhuman objects, such as sexual attractions to particular articles of clothing (shoes, underwear); commonly called sexual deviations.

parasympathetic division The subdivision of the autonomic nervous system that decreases physiological arousal and helps return the body to a calmer, more relaxed state. It also stimulates digestion during eating.

parentese A way of speaking to young children in which the adult speaks in a voice that is slower and higher than normal, emphasizes and stretches out each word, uses very simple sentences, and repeats words and phrases. Formerly known as motherese.

parietal lobe An area of the cortex located directly behind the frontal lobe. Its functions include processing sensory information from body parts, which includes touching, locating positions of limbs, and feeling temperature and pain; and carrying out several cognitive functions, such as attending to and perceiving objects.

Parkinson's disease A condition caused by the destruction of neurons that produce the neurotransmitter dopamine. Symptoms include tremors and shakes in the limbs, a slowing of voluntary movements, and feelings of depression. As the disease progresses, patients develop a peculiar shuffling walk and may suddenly freeze in space for minutes or hours at a time.

partial reinforcement A schedule of reinforcement in which the response is reinforced only some of the time.

passion In Sternberg's triangular theory of love, the component of love associated with feeling physically aroused and attracted to someone.

passionate love A condition that is associated with continuously thinking about the loved one and is accompanied by warm sexual feelings and powerful emotional reactions.

pathological aging Acceleration of the aging process, which may be caused by genetic defects, physiological problems, or diseases.

peg method A mnemonic device, or encoding technique, that creates associations between number-word rhymes and items to be memorized.

perception The experience of a meaningful pattern or image that the brain assembles from thousands of individual meaningless sensations; a perception is normally changed, biased, colored, or distorted by a person's unique set of experiences.

perceptual constancy Our tendency to perceive sizes, colors, brightness, and shapes as remaining the same even though their physical characteristics are constantly changing.

perceptual sets Learned expectations that are based on our personal, social, or cultural experiences. These expectations automatically add information, meaning, or feelings to our perceptions and thus change or bias our perceptions.

perceptual speed The rate at which we can identify a particular sensory stimulus; this rate slows down noticeably after age 60.

peripheral cues Hunger cues associated with changes in blood chemistry or signals from digestive organs.

peripheral nervous system All the nerves that extend from the spinal cord and carry messages to and from various muscles, glands, and sense organs located throughout the body. It has two divisions: the somatic nervous system and the autonomic nervous system.

peripheral route for persuasion Approaches to persuasion that emphasize emotional appeal, focus on personal traits, and generate positive feelings.

peripheral theories of emotions Theories that attribute our subjective feelings primarily to our body's physiological changes.

permissive parents Parents who are less controlling and behave with a nonpunishing and accepting attitude toward their children's impulses, desires, and actions. They consult with their children about policy decisions, make few demands, and tend to use reason rather than direct power.

person perception The process by which we form impressions of, and make judgments about, the traits and characteristics of others.

person schemas Social schemas including our judgments about the traits that we and others possess.

person-situation interaction The interaction between a person's traits and the effects of being in a particular situation, which, according to Mischel, determines the person's behavior.

personal fable Adolescents' belief that they are invulnerable, unique, and special.

personal factors According to social cognitive theory, factors that include our emotional makeup and our biological and genetic influences and that help to shape our personalities.

personal identity *See* identity.

personality A combination of long-lasting and distinctive behaviors, thoughts, motives, and emotions that typify how we react and adapt to other people and situations. *See also* theory of personality.

personality development *See* social development.

personality disorder Any psychological disorder characterized by inflexible, long-standing, maladaptive traits that cause significantly impaired functioning or great distress in one's personal and social life.

personality tests Tests used to measure a person's observable traits and behaviors and unobservable characteristics. In addition, some are used to identify personality problems and psychological disorders, as well as to predict how a person might behave in the future. Objective personality tests (self-report questionnaires), such as the MMPI, consist of specific statements or questions to which the person responds with specific answers; projective tests, such as the Rorschach inkblot test, have no set answers but consist of ambiguous stimuli that a person interprets or makes up stories about.

pessimism A relatively stable personality trait that leads one to believe and expect that bad things will happen. It is one of the personality factors associated with increased stress levels and chances of developing psychosomatic symptoms. *See* optimism.

PET *See* positron emission tomography.

phallic stage Freud's third psychosexual stage, lasting from the ages of about 3 to 6 years, in which the infant's pleasure seeking is centered on the genitals.

phantom limb The experience of sensations and feelings coming from a limb that has been amputated. The sensations and feelings are extremely vivid, as if the amputated limb were still present.

phenomenological perspective The idea that our perspective of the world, whether or not it is accurate, becomes our reality. This idea is stressed in humanistic theories.

phenothiazines The first group of drugs to reduce schizophrenic symptoms, such as delusions and hallucinations. Discovered in the early 1950s, the phenothiazines operate by blocking or reducing the effects of the neurotransmitter dopamine.

phi movement The illusion that stationary lights are moving. The illusion of movement—today called apparent motion—is created by flashing closely positioned stationary lights at regular intervals.

phobia An anxiety disorder characterized by an intense and irrational fear that is out of all proportion to the danger elicited by the object or situation. In comparison, fear is a realistic response to a threatening situation.

phonemes The basic sounds of consonants and vowels.

phonology Rules specifying how we make the meaningful sounds used by a particular language.

photographic memory The ability to form sharp, detailed visual images after examining a picture or page for a short period of time and to recall the entire image at a later date.

Piaget's cognitive stages Four different stages—the sensorimotor, preoperational, concrete operations, and formal operations stages—each of which is more advanced than the preceding stage because it involves new reasoning and thinking abilities.

pica A behavioral disorder in which individuals eat inedible objects or unhealthy substances. Pica can lead to serious physical problems, including lead poisoning, intestinal blockage, and parasites, and is most often seen in individuals with mental retardation.

pitch Our subjective experience of how low or high a sound is. The brain calculates pitch from the speed (frequency) of the sound waves. The frequency of sound waves is measured in cycles, which refers to how many sound waves occur in 1 second.

pituitary gland A key component of the endocrine system, which hangs directly below the hypothalamus, to which it is connected by a narrow stalk. Its anterior section regulates growth and controls much of the endocrine system, while its posterior section regulates water and salt balance.

place theory The theory that the brain perceives the pitch of a sound by receiving information about where on the basilar membrane a given sound vibrates the most; it applies to medium and higher pitches.

placebo An intervention—taking a pill, receiving an injection, or undergoing an operation—that resembles medical therapy but that, in fact, has no medical effects.

placebo effect A change in the patient's illness that is attributable to an imagined treatment rather than to a medical treatment.

placenta An organ that connects the blood supply of the mother to that of the fetus. The placenta acts like a filter, allowing oxygen and nutrients to pass through while keeping out certain toxic or harmful substances.

pleasure principle The satisfaction of drives and avoidance of pain, without concern for moral restrictions or society's regulations. According to Freud, this is the id's operating principle.

polygraph tests Tests based on the theory that, if a person tells a lie, he or she will feel some emotion, such as guilt or fear. Feeling guilty or fearful will usually be accompanied by involuntary physiological responses, which are difficult to suppress or control and can be measured with a machine called a polygraph.

polymorphic gene A gene that has more than one version—for example, dominant and recessive.

pons A bridge that connects the spinal cord with the brain and parts of the brain with one another. Cells in the pons manufacture chemicals involved in sleep.

positive psychology The scientific study of optimal human functioning, focusing on the strengths and virtues that enable individuals and communities to thrive. It aims to better understand the positive, adaptive, and fulfilling aspects of human life.

positive punishment The presentation of an aversive stimulus (for example, spanking) after a response. The aversive stimulus decreases the chances that the response will recur.

positive regard Love, sympathy, warmth, acceptance, and respect, which we crave from family, friends, and people important to us.

positive reinforcement The presentation of a stimulus that increases the probability of a behavior's recurrence.

positive reinforcer A stimulus that increases the likelihood that a response will occur again.

positive symptoms of schizophrenia Symptoms that reflect a distortion of normal functions. Distorted thinking results in delusions; distorted perceptions result in hallucinations; and distorted language results in disorganized speech.

positron emission tomography (PET) A technique to measure the function of the living brain. A slightly radioactive solution is injected into the blood, and the amount of radiation absorbed by the brain cells is measured. Very active brain cells—neurons—absorb more radioactive solution than less active ones. A computer transforms the different levels of absorption into colors that indicate the activity of neurons. The colors red and yellow indicate maximum activity of neurons; blue and green indicate minimal activity.

postconventional level Kohlberg's highest level of moral reasoning, at which moral decisions are made after carefully thinking about all the alternatives and striking a balance between human rights and the laws of society.

posterior pituitary The rear part of the pituitary gland, a key component of the endocrine system. It regulates water and salt balance.

posthypnotic amnesia Inability to remember what happened during hypnosis, prompted by a specific suggestion from the hypnotist.

posthypnotic suggestion A suggestion given to the subject during hypnosis about performing a particular behavior, in response to a predetermined cue, when the subject comes out of hypnosis.

posttraumatic stress disorder (PTSD) A disabling condition that results from direct personal experience of an event that involves actual or threatened death or serious injury or from witnessing such an event or hearing that such an event has happened to a family member or close friend.

precognition The ability to foretell events.

preconventional level Kohlberg's lowest level of moral reasoning. It consists of two stages: At stage 1, moral decisions are based primarily on fear of punishment or the need to be obedient; at stage 2, moral reasoning is guided most by satisfaction of one's self-interest, which may involve making bargains.

prejudice An unfair, biased, or intolerant attitude toward another group of people.

premature ejaculation Persistent or recurrent absence of voluntary control over ejaculation, in that the male ejaculates with minimal sexual stimulation before, upon, or shortly after penetration and before he wishes to; also called rapid ejaculation.

prenatal period The period from conception to birth, which lasts about 266 days (about nine months). It is divided into three phases: germinal, embryonic, and fetal. During the prenatal period, a single cell will divide and grow to form 200 billion cells.

preoperational stage The second of Piaget's cognitive stages, lasting from the ages of about 2 to 7 years. During this stage, children learn to use symbols (such as words or mental images) to think about things that are not present and to help solve simple problems.

preparedness The innate or biological tendency of animals and humans to recognize, attend to, and store certain cues over others, as well as to associate some combinations of conditioned and unconditioned stimuli more easily than others. Also called prepared learning.

primacy effect Better recall, or improvement in retention, of information presented at the beginning of a task.

primacy-recency effect Better recall of information presented at the beginning and end of a task.

primary appraisal Our initial, subjective evaluation of a situation, in which we balance the demands of a potentially stressful situation against our ability to meet them.

primary auditory cortex An area at the top edge of the temporal lobe that transforms nerve impulses (electrical signals) into basic auditory sensations, such as meaningless sounds and tones of varying pitch and loudness. Next, it sends impulses (sensations) to the auditory association areas.

primary reinforcer A stimulus, such as food, water, or sex, that is innately satisfying and requires no learning on the part of the subject to become pleasurable.

primary visual cortex A small area, located at the back of each occipital lobe, that receives electrical signals from receptors in the eyes and transforms these signals into meaningless, basic visual sensations, such as lights, lines, shadows, colors, and textures.

principle of bidirectionality The idea that a child's behaviors influence how his or her parents respond and, in turn, the parents' behaviors influence how the child responds.

proactive interference A forgetting process in which information that we learned earlier blocks or disrupts the retrieval of related information that was learned later.

problem-focused coping Solving a problem by seeking information, changing our own behavior, or taking whatever action is necessary.

problem solving Searching for some rule, plan, or strategy in order to reach a certain goal that is currently out of reach.

procedural memory Memories of performing motor or perceptual tasks (playing sports), carrying out habitual behaviors (brushing teeth), and responding to stimuli because of classical conditioning (fearing spiders). We cannot retrieve these memories, and we are not conscious of them.

processing speed The rate at which we encode information into long-term memory or recall or retrieve information from long-term memory; this rate slows down after age 60.

procrastination The tendency to always put off completing a task to the point of feeling anxious or uncomfortable about one's delay.

prodigy A child who shows unusual talent, ability, or genius at a very early age and does not have mental retardation. A small percentage of autistic children, who have some degree of mental retardation, may also show unusual artistic or mathematical abilities; they are called savants.

progressive relaxation An exercise in which the major muscle groups of the body are tensed and relaxed repeatedly until the individual can relax any group of muscles at will.

projection Unconsciously transferring unacceptable traits to others.

projective tests Tests in which the subject is presented with some type of ambiguous stimulus—such as a meaningless object or ambiguous photo—and then asked to make up a story about the stimulus. The assumption is that the person will project conscious or unconscious feelings, needs, and motives in his or her responses.

prosocial behavior Any behavior that benefits others or has positive social consequences. Also called helping.

prototype theory The idea that we form a concept by first constructing a prototype of an object—that is, a mental image based on its average characteristics. Once we have formed a set of prototypes, we identify new objects by matching them against our prototypes.

proximity rule A perceptual rule stating that, in organizing stimuli, objects that are physically close to one another will be grouped together.

proximodistal principle The rule that parts closer to the center of the infant's body develop before parts that are farther away.

psi The processing of information or transfer of energy by methods that have no known physical or biological mechanisms and that seem to stretch the laws of physics.

psilocybin A hallucinogen, the active ingredient in magic mushrooms. Low doses produce pleasant and relaxed feelings; medium doses produce distortions in the perception of time and space; and high doses produce distortions in perceptions and body image and sometimes hallucinations.

psychiatrist A medical doctor (M.D.) who has taken a psychiatric residency, which involves additional training in pharmacology, neurology, psychopathology, and therapeutic techniques. In diagnosing the possible causes of abnormal behaviors, psychiatrists focus on biological factors; they tend to view mental disorders as diseases and to treat them with drugs. Psychiatrists who receive additional training in psychoanalytic institutes are called psychoanalysts.

psychoactive drugs Chemicals that affect the nervous system and, as a result, may alter consciousness and awareness, influence sensations and perceptions, and modify moods and cognitive processes. Some are legal (coffee, alcohol, and tobacco), and some are illegal (marijuana, heroin, cocaine, and LSD).

psychoanalysis A form of psychotherapy based on the idea that each of us has an unconscious part that contains ideas, memories, desires, or thoughts that have been hidden or repressed because they are psychologically dangerous or threatening to our self-concept. To protect our self-concept, we automatically build a mental barrier that we cannot voluntarily remove. But the presence of these thoughts and desires gives rise to unconscious conflicts, which, in turn, can result in psychological and physical symptoms and mental disorders.

psychoanalyst *See* psychiatrist.

psychoanalytic approach A psychological viewpoint that stresses the influence of unconscious fears, desires, and motivations on thoughts and behaviors and also the impact of childhood experiences on the development of later personality traits and psychological problems. As applied to mental disorders, this approach traces their origin to unconscious conflicts or problems with unresolved conflicts at one or more of Freud's psychosexual stages. Treatment of mental disorders, in this approach, centers on the therapist's helping the patient to identify and resolve his or her unconscious conflicts.

psychobiology The scientific study of the physical and chemical changes that occur during stress, learning, and emotions, as well as how our genetic makeup and nervous system interact with our environments and influence our behaviors.

psychodynamic theory of personality *See* Freud's psychodynamic theory of personality.

psychokinesis The ability to exert mind over matter—for example, by moving objects without touching them.

psychological assessment The use of various tools—including psychological tests and interviews—to measure characteristics, traits, or abilities in order to understand behavior and predict future performance or behavior.

psychological factors Performance anxiety, sexual trauma, guilt, or failure to communicate, all of which may lead to sexual problems.

psychological sex factors Factors involved in the development of a gender identity, gender role, and sexual orientation, as well as in difficulties in sexual performance or enjoyment.

psychologist An individual who has completed four to five years of postgraduate education and has obtained a PhD in psychology; in some states, an individual with a master's degree.

psychology The systematic, scientific study of behaviors and mental processes.

psychometric approach An approach to the assessment of intelligence that measures or quantifies cognitive abilities or factors that are thought to be involved in intellectual performance.

psychometrics A subarea of psychology concerned with the development of tests to assess an individual's abilities, skills, intelligence, personality traits, and abnormal behaviors in a wide range of settings—school, the workplace, or a clinic.

psychoneuroimmunology The study of the relationship among the central nervous system, the endocrine system, and psychosocial factors such as cognitive reactions to stressful events, the individual's personality traits, and social influences.

psychosexual stages According to Freud, five developmental periods—the oral, anal, phallic, latency, and genital stages—each marked by potential conflict between parent and child. The conflicts arise as the child seeks pleasure from different bodily areas associated with sexual feelings (erogenous zones). Freud emphasized that the child's first five years were most important in social and personality development.

psychosocial factors Underlying personality traits, amount of social support, and ability to deal with stressful life events—these factors are believed to combine and interact with predisposing biological factors to either increase or decrease a person's vulnerability to the development and maintenance of a mood disorder.

psychosocial hunger factors Learned associations between food and other stimuli, such as snacking while watching television; sociocultural influences, such as pressures to be thin; and various personality problems, such as depression, dislike of body image, or low self-esteem.

psychosocial stages According to Erikson, eight developmental periods during which an individual's primary goal is to satisfy desires associated with social needs: The eight periods are associated, respectively, with issues of trust, autonomy, initiative, industry, identity, intimacy, generativity, and ego integrity.

psychosomatic symptoms Real, physical, and often painful symptoms, such as headaches, muscle pain, and stomach problems, that are caused by psychological factors, such as worry, tension, and anxiety.

psychotherapy Approaches to treating psychological problems that share three characteristics: verbal interaction between therapist and client(s); the development of a supportive relationship during which a client can bring up and discuss traumatic or bothersome experiences that may have led to current problems; and analysis of the client's experiences and/or suggested ways for the client to deal with or overcome his or her problems.

puberty A developmental period, corresponding to the ages of 9 to 17 years, when the individual experiences significant biological changes and, as a result, develops secondary sexual characteristics and reaches sexual maturity.

punishment A consequence that occurs after behavior and decreases the likelihood that that behavior will recur.

pupil The round opening at the front of the eye that allows light waves to pass through into the eye's interior.

Q

quantum personality change A sudden and radical or dramatic shift in personality, beliefs, or values.

questionnaire A method for obtaining information by asking subjects to read a list of written questions and to check off, or rate their preference for, specific answers.

R

random selection A research design such that each subject in a sample population has an equal chance of being selected to participate in the experiment.

range The different or interval between the highest and lowest values in a distribution.

rape myths Misinformed false beliefs about women that are frequently held by rapists as well as by other men.

rationalization Inventing acceptable excuses for behaviors that make us feel anxious.

reaction formation Turning unacceptable wishes into acceptable behaviors.

reaction range The extent to which traits, abilities, or IQ scores may increase or decrease as a result of interaction with environmental factors.

reaction time The rate at which we respond (see, hear, move) to some stimulus; this rate slows down noticeably after age 60.

reactive attachment disorder A psychiatric illness characterized by serious problems in emotional attachments to others, beginning before age 5. Symptoms include resisting comfort and affection by parents, being superficially engaging and overly friendly with strangers, having poor peer relationships, and engaging in destructive behaviors.

real motion Our perception of any stimulus or object that actually moves in space; the opposite of apparent motion.

real self According to Rogers, the self that is based on our actual experiences and represents how we really see ourselves; its complement is the ideal self.

reality principle A policy of satisfying a wish or desire only if a socially acceptable outlet is available. According to Freud, this is the ego's operating principle.

recall Retrieval of previously learned information without the aid of or with very few external cues.

recency effect Better recall, or improvement in retention, of information presented at the end of a task.

recessive gene A type of polymorphic gene that determines the development of a specific trait only when it is inherited from both parents.

recognition The identification of previously learned information with the help of external cues.

reflex An unlearned, involuntary reaction to some stimulus. The neural connections of the network underlying a reflex are prewired by genetic instructions.

reinforcement A consequence that occurs after behavior and increases the likelihood that that behavior will recur.

relative size In three-dimensional vision, a monocular depth cue that results when we expect two objects to be the same size and they are not. In that case, the larger of the objects will appear closer, and the smaller will appear to be farther away.

reliability The extent to which a test is consistent: A person's score on a test at one point in time should be similar to the score obtained by the same person on a similar test at a later point in time.

REM behavior disorder A disorder, usually found in older people, in which the voluntary muscles are not paralyzed during REM sleep; sleepers can and do act out their dreams.

REM (rapid eye movement) sleep The stage of sleep in which our eyes move rapidly back and forth behind closed eyelids. This stage makes up 20% of our sleep time; in a normal night, we experience five or six periods of REM sleep, each one lasting 15–45 minutes. REM brain waves, which have a high frequency and a low amplitude, look very similar to the beta waves that are recorded when we are wide awake and alert; the body's voluntary muscles, however, are paralyzed. Dreams usually occur during REM sleep.

REM rebound The tendency of individuals to spend proportionately longer in the REM stage of sleep after they have been deprived of REM sleep on previous nights.

repair theory A theory of sleep suggesting that activities during the day deplete key factors in the brain or body that are replenished or repaired by sleep.

repression According to Freud, a mental process that automatically hides emotionally threatening or anxiety-producing information in the unconscious. Repressed information cannot be retrieved voluntarily, but something may cause it to be released and to reenter the person's consciousness at a later time.

resiliency Various personal, family, or environmental factors that compensate for increased life stresses so that expected problems do not develop.

resistance In psychotherapy, especially psychoanalysis, the client's reluctance to work through or deal with feelings or to recognize unconscious conflicts and repressed thoughts.

resistance stage The second stage in the general adaptation syndrome. In reaction to continued stress, most physiological responses return to normal levels, but the body uses up great stores of energy.

resting state A condition in which the axon, like a battery, has a charge, or potential, because the axon membrane separates positive ions on the outside from negative ions on the inside.

reticular formation A column of brain cells that arouses and alerts the forebrain and prepares it to receive information from all the senses. It plays an important role in keeping the forebrain alert and producing a state of wakefulness. Animals or humans whose reticular formation is seriously damaged lapse into permanent unconsciousness or coma.

retina A thin film, located at the very back of the eyeball, that contains cells, called photoreceptors, that are extremely sensitive to light. The retina consists of three layers, the third and deepest of which contains two kinds of photoreceptors, rods and cones, that perform transduction; that is, they change light waves into nerve impulses.

retinal disparity A binocular depth cue that depends on the distance between the two eyes. Because of their different positions, the two eyes receive slightly different images. The difference between these images is the retinal disparity. The brain interprets large retinal disparity to mean a close object and small retinal disparity to mean a distant object.

retrieval cues Mental reminders that we create by forming vivid mental images of information or associating new information with information that we already know. Forgetting can result from not taking the time to create effective retrieval cues.

retrieving The process of getting or recalling information that has been placed into short-term or long-term storage.

retroactive interference A forgetting process in which information that we learned later blocks or disrupts the retrieval of related information that we learned earlier.

reuptake The process by which some neurotransmitters, such as dopamine, are removed from the synapse by being transported back into the end bulbs.

reward/pleasure center The part of the brain that includes the nucleus accumbens and ventral tegmental area and involves several neurotransmitters, especially dopamine. Combined with other brain areas, it forms a neural circuit that produces rewarding and pleasurable feelings.

rods Photoreceptors containing the chemical rhodopsin, which is activated by small amounts of light. Because rods are extremely light sensitive, they allow us to see in dim light but to see only black, white, and shades of gray.

role schemas Social schemas based on the jobs people perform or the social positions they hold.

Rorschach inkblot test A projective test used to assess personality in which a person is shown a series of ten inkblots and then asked to describe what he or she sees in each.

rules of organization Rules identified by Gestalt psychologists that specify how our brains combine and organize individual pieces or elements into a meaningful whole—that is, a perception.

S

SAD *See* seasonal affective disorder.

savants Autistic individuals who show some incredible memory, music, or drawing talent. They represent about 10% of the total number of autistics.

schedule of reinforcement In conditioning, a program or rule that determines how and when a response will be followed by a reinforcer.

schemas Mental categories that, like computer files, contain knowledge about people, events, and concepts. Because schemas influence which stimuli we attend to, how we interpret stimuli, and how we respond to stimuli, they can bias and distort our thoughts, perceptions, and behaviors. *See also* event schemas, gender schemas, person schemas, role schemas, and self schemas.

schizophrenia A serious mental disturbance that lasts at least six months and includes at least two of the following symptoms: delusions, hallucinations, disorganized speech, grossly disorganized behavior, and decreased emotional expression. These symptoms interfere with personal or social functioning. *See also* Type I and Type II schizophrenia.

schizotypical personality disorder A disorder characterized by acute discomfort in close relationships, distortions in thinking, and eccentric behavior. It is found in 3–5% of the population.

scientific method A general approach to gathering information and answering questions so that errors and biases are minimized.

scripts *See* event schemas.

seasonal affective disorder (SAD) A pattern of depressive symptoms that cycle with the seasons, typically beginning in fall or winter. The depression is accompanied by feelings of lethargy, excessive sleepiness, overeating, weight gain, and craving for carbohydrates.

secondary appraisal Deciding what we can do to deal with a potentially stressful situation. We can choose some combination of problem-focused coping, which means doing something about the problem, and emotion-focused coping, which means dealing with our emotions.

secondary reinforcer Any stimulus that has acquired its reinforcing power through experience; secondary reinforcers are learned, for example, by being paired with primary reinforcers or other secondary reinforcers.

secure attachment An emotional bond characteristic of infants who use their parent as a safe home base from which they can wander off and explore their environments.

self How we see or describe ourselves; also called self-concept. The self is made up of many self-perceptions, abilities, personality characteristics, and behaviors that are organized so as to be consistent with one another.

self-actualization Our inherent tendency to reach our true potentials. The concept of self-actualization, developed by Maslow, is central to humanistic theories.

self-actualization theory *See* self theory.

self-actualizing tendency An inborn tendency for us to develop all of our capacities in ways that best maintain and benefit our lives.

self-concept *See* self.

self-efficacy Our personal beliefs regarding how capable we are of exercising control over events in our lives, such as completing specific tasks and behaviors.

self-esteem How much an individual likes himself or herself; it includes feelings of self-worth, attractiveness, and social competence.

self-fulfilling prophecy A situation in which a person has a strong belief or makes a statement (prophecy) about a future behavior and then acts, usually unknowingly, to fulfill or carry out that behavior.

self-handicapping A tendency to adopt tactics that are likely to fail and then to use those tactics as excuses for failures in performance, activities, or achieving goals.

self-identity *See* identity.

self-perception theory The idea, developed by Daryl Bem, that we first observe or perceive our own behavior and then, as a result, change our attitudes.

self-report questionnaires *See* objective personality tests.

self schemas Social schemas containing personal information about ourselves. They can influence how we behave as well as what we perceive and remember.

self-serving bias Attributing our successes to our dispositions or personality traits and our failures to the situations.

self theory Rogers's humanistic theory, based on two major assumptions: that personality development is guided by each person's unique self-actualization tendency; and that each of us has a personal need for positive regard.

semantic memory A type of declarative memory consisting of factual knowledge about the world, concepts, word definitions, and language rules.

semantics A set of rules that specify the meanings of words or phrases when they appear in various sentences or contexts.

semicircular canals Structures of the vestibular system in the inner ear that resemble bony arches and are set at different angles. Each canal is filled with fluid that moves in response to the movement of the head and aids in sensing the position of the head and maintaining balance.

sensation Our first awareness of some outside stimulus; relatively meaningless bits of information that result when the brain processes electrical signals that come from the sense organs.

sensitive period *See* critical period.

sensorimotor stage The first of Piaget's cognitive stages, lasting from birth to about age 2 years. During this stage, infants interact with and learn about their environments by relating their sensory experiences (such as hearing and seeing) to their motor actions (mouthing and grasping).

sensory memory An initial memory process that receives and holds environmental information in its raw form for a brief period of time, from an instant to several seconds.

sensory neurons *See* afferent neurons.

sentence stage The fourth stage in acquiring language, which begins at about 4 years of age. Sentences range from three to eight words in length and indicate a growing knowledge of the rules of grammar.

separation anxiety An infant's distress—as indicated by loud protests, crying, and agitation—whenever his or her parents temporarily leave.

set point A certain level of body fat (adipose tissue) that our body strives to maintain constant throughout our lives; the set point is an inherited characteristic.

sex chromosome The sperm or the egg. Each contains only 23 chromosomes, on which are the genes bearing the instructions that determine the sex of the child.

sex (gender) differences in the brain Structural or functional differences in cognitive, behavioral, or brain processes that arise from being male or female.

sex hormones Chemicals, secreted by glands, that circulate in the bloodstream and influence the brain, other body organs, and behaviors. The major male sex hormones secreted by the testes are androgens, such as testosterone; the major female sex hormones secreted by the ovaries are estrogens.

sexual dysfunctions Problems of sexual arousal or orgasm that interfere with adequate functioning during sexual behavior.

sexual orientation A person's pattern of primary sexual arousal: by members of his or her own sex, the opposite sex, or both sexes; also called sexual preference.

shape constancy Our tendency to see an object as remaining the same shape when viewed at different angles—that is, despite considerable change in the shape of its image on the retina.

shaping In operant conditioning, a procedure in which an experimenter successively reinforces behaviors that lead up to or approximate the desired behavior.

short-term dynamic psychotherapy A shortened version of psychoanalysis. It emphasizes a limited time for treatment (20–30 sessions) and focuses on limited goals, such as solving a relatively well-defined problem. Therapists take an active and directive role by identifying and discussing the client's problems, resolving issues of transference, interpreting the patient's behaviors, and offering an opportunity for the patient to foster changes in behavior and thinking that will result in more active coping and an improved self-image.

short-term memory A process that can hold a limited amount of information—an average of seven items—for a short time (2–30 seconds), which can be lengthened if you rehearse the information. Sometimes called working memory.

shyness The tendency to feel tense, worried, or awkward in social situations.

similarity rule A perceptual rule stating that, in organizing stimuli, we group together elements that appear similar.

simplicity rule A perceptual rule stating that stimuli are organized in the simplest way possible.

single-word stage The second stage in acquiring language, which begins when the child is about 1 year old. Infants say single words that usually refer to what they can see, hear, or feel.

situational attributions *See* external attributions.

size constancy Our tendency to perceive objects as remaining the same size even when their images on the retina are continuously growing or shrinking.

skewed distributions Distributions in which more data fall toward one side of the scale than toward the other.

sleep A condition in which we pass through five different stages, each with its own level of consciousness, awareness, responsiveness, and physiological arousal. In the deepest stage of sleep, we enter a state that borders on unconsciousness.

sleep apnea A condition characterized by a cycle in which a sleeper stops breathing for intervals of 10 seconds or longer, wakes up briefly, resumes breathing, and returns to sleep. This cycle can leave apnea sufferers exhausted during the day but oblivious to the cause of their tiredness. It is more common among habitual snorers.

sleepwalking Walking or carrying out behaviors while still asleep. Sleepwalkers generally are clumsy and have poor coordination but can avoid objects; they can engage in very limited conversations. Sleepwalking behaviors can include dressing, eating, performing bathroom functions, and even driving a car. Sleepwalking usually occurs during stage 3 or stage 4 (delta) sleep.

social cognitive learning A form of learning that results from watching, imitating, and modeling and does not require the observer to perform any observable behavior or receive any observable reward. Formerly called observational learning.

social cognitive theory The theory that grew out of the research of a number of psychologists—Rotter, Bandura, and Mischel—that says that personality development is primarily shaped by three forces: environmental conditions, cognitive-personal factors, and behavior, which all interact to influence how we evaluate, interpret, organize, and apply information. *See also* Bandura's social cognitive theory.

social comparison theory The idea that we are driven to compare ourselves to others who are similar to us, so that we can measure the correctness of our attitudes and beliefs. According to Festinger, this drive motivates us to join groups.

social development How a person develops a sense of self or self-identity, develops relationships with others, and develops the skills useful in social interactions.

social facilitation An increase in performance in the presence of a crowd.

social inhibition A decrease in performance in the presence of a crowd.

social needs Needs that are acquired through learning and experience.

social neuroscience An emerging area of research that examines social behavior by combining biological and social approaches. It focuses on understanding how social behavior influences the brain, and vice versa.

social norms approach Relating to abnormality, the idea that a behavior is considered abnormal if it deviates greatly from accepted social standards, values, or norms.

social phobias Irrational, marked, and continuous fear of performing in social situations. The individuals fear that they will humiliate or embarrass themselves.

social psychology A broad field whose goals are to understand and explain how our thoughts, feelings, perceptions, and behaviors are influenced by interactions with others. It includes the study of stereotypes, prejudices, attitudes, conformity, group behaviors, and aggression.

social role theory The theory that emphasizes the importance of social and cultural influences on gender roles and states that gender differences between males and females arise from different divisions of labor.

social support A stress-reducing factor that includes three components: having a group or network of family or friends who provide strong social attachments; being able to exchange helpful resources among family or friends; and feeling, or making appraisals, that we have supportive relationships or behaviors.

socially oriented group A group in which members are primarily concerned about fostering and maintaining social relationships among the members of the group.

sociobiology theory *See* evolutionary theory.

sociocognitive theory of hypnosis The idea that the impressive effects of hypnosis are due to social influences and pressures as well as the subject's personal abilities. For another view, *see* altered state theory of hypnosis.

sodium pump A chemical transport process that picks up any sodium ions that enter the axon's chemical gates and returns them back outside. In this way, the sodium pump is responsible for keeping the axon charged by returning and keeping sodium ions outside the axon membrane.

somatic nervous system A network of nerves that are connected either to sensory receptors or to muscles that you can move voluntarily, such as muscles in your limbs, back, neck, and chest. Nerves in the somatic nervous system usually contain two kinds of fibers: afferent, or sensory, fibers that carry information from sensory receptors in the skin, muscles, and other organs to the spinal cord and brain; and efferent, or motor, fibers that carry information from the brain and spinal cord to the muscles.

somatization disorder A somatoform disorder that begins before age 30, lasts several years, and is characterized by multiple symptoms—including pain, gastrointestinal, sexual, and neurological symptoms—that have no physical causes but are triggered by psychological problems or distress.

somatoform disorder A pattern of recurring, multiple, and significant bodily (somatic) complaints that extend over several years. The physical symptoms (pain, vomiting, paralysis, blindness) are not under voluntary control, have no known physical causes, and are believed to be caused by psychological factors.

somatosensory cortex A narrow strip of the cortex that is located at the front edge of the parietal lobe and extends down its side. It processes sensory information about touch, location of limbs, pain, and temperature. The right somatosensory cortex receives information from the left side of the body, and vice versa.

sound waves The stimuli for hearing, or audition. Similar to ripples on a pond, sound waves travel through space with varying heights and speeds. Height, or amplitude, is the distance from the bottom to the top of a sound wave; speed, or frequency, is the number of sound waves that occur within 1 second.

source misattribution A memory error that results when a person has difficulty deciding which of two or more sources a memory came from: Was the source something the person saw or imagined, or was it a suggestion?

Spearman's *g* *See* two-factor theory.

specific phobias Unreasonable, marked, and persistent fears triggered by anticipation of, or exposure to, a specific object or situation (flying, heights, spiders, seeing blood); formerly called simple phobias.

split-brain operation A procedure for moderating severe, uncontrollable seizures by cutting the corpus callosum, a wide band of nerve fibers that connects the right and left hemispheres.

spontaneous recovery In classical conditioning, the temporary occurrence of the conditioned response to the presence of the conditioned.

stage 1 In sleep, a stage lasting 1–7 minutes in which the individual gradually loses responsiveness to stimuli and experiences drifting thoughts and images. This stage marks the transition from wakefulness to sleep and is characterized by the presence of theta waves, which are lower in amplitude and frequency (3–7 cycles per second) than alpha waves.

stage 2 In sleep, the stage that marks the beginning of what we know as sleep; subjects awakened in stage 2 report having been asleep. EEG tracings show high-frequency bursts of brain activity called sleep spindles.

stages 3 and 4 About 30–45 minutes after drifting off to sleep, we pass rapidly through stage 3 and enter stage 4 sleep, a stage characterized by delta waves, which have very high amplitude and very low frequency (less than 4 cycles per second). Stage 4 is often considered the deepest stage of sleep because it is the most difficult from which to be awakened. During stage 4, heart rate, respiration, temperature, and blood flow to the brain are reduced, and there is a marked secretion of growth hormone, which controls many aspects of metabolism, physical growth, and brain development. This stage is also called slow-wave or delta sleep.

stages of sleep Distinctive changes in the electrical activity of the brain and accompanying physiological responses of the body that occur as we pass through different stages of sleep. *See also* stage 1, stage 2, stages 3 and 4.

standard deviation A statistic indicating how widely all the scores in a distribution are scattered above and below the mean.

standardized test A technique to obtain information by administering a psychological test that has been standardized, which means that the test has been given to hundreds of people and shown to reliably measure thought patterns, personality traits, emotions, or behaviors.

state-dependent learning The idea that we recall information more easily when we are in the same physiological or emotional state or setting as when we originally encoded the information.

statistical frequency approach In definitions of abnormality, the idea that a behavior may be considered abnormal if it occurs rarely or infrequently in relation to the behaviors of the general population.

statistical procedures In experiments, procedures to determine whether differences observed in dependent variables (behaviors) are due to independent variables (treatment) or to error or chance occurrence.

statistics Tools researchers use to analyze and summarize large amounts of data.

stem cells Cells formed in the embryo that have the amazing capacity to change into any of the 220 cells that make up a human body, including skin, heart, liver, bones, and neurons.

stereotaxic procedure A method used for introducing material at a precise location within the brain. The patient's head is fixed in a holder, and a small hole is drilled through the skull. The holder has a syringe that can be precisely guided to a predetermined location in the brain.

stereotypes Widely held beliefs that people have certain traits because they belong to a particular group. Stereotypes are often inaccurate and frequently portray the members of less powerful, less controlling groups more negatively than members of more powerful, more controlling groups.

Sternberg's triangular theory of love The idea that love has three components: passion, intimacy, and commitment. Passion is feeling physically aroused and attracted to someone; intimacy is feeling close and connected to someone, through sharing and communicating; and commitment is pledging to nourish the feelings of love and actively maintain the relationship.

Sternberg's triarchic theory The idea that intelligence can be divided into three ways of gathering and processing information (*triarchic* means "three"): using analytical or logical thinking skills that are measured by traditional intelligence tests; using problem-solving skills that require creative thinking, the ability to deal with novel situations, and the ability to learn from experience; and using practical thinking skills that help a person adjust to, and cope with, his or her sociocultural environment.

stimulants Drugs, such as cocaine, amphetamines, caffeine, and nicotine, that increase activity in the nervous system and result in heightened alertness, arousal, and euphoria and decreased appetite and fatigue.

stimulus substitution The theory that, in classical conditioning, a neural bond or association is formed between the neutral stimulus and unconditioned stimulus. After repeated trials, the neutral stimulus becomes the conditioned stimulus, which, in turn, substitutes for the unconditioned stimulus. Thereafter, the conditioned stimulus elicits a response similar to that of the unconditioned stimulus.

stomach The body organ that monitors the amount and kinds of nutrients our body needs to restore our depleted stores of fuel. In addition, after we eat a meal, the stomach's walls are distended and their stretch receptors signal fullness or time to stop eating.

storing The process of placing encoded information into relatively permanent mental storage for later recall.

stress The anxious or threatening feeling that comes when we interpret or appraise a situation as being more than our psychological resources can adequately handle.

stress management program A program to reduce anxiety, fear, and stressful experiences by using a variety of strategies to change three different aspects of our lives: thoughts (appraisals), behaviors, and physiological responses.

structuralism An early school of psychological thought that emphasized the study of the basic elements—primarily sensations and perceptions—that make up conscious mental experiences. Structuralists argued that we can understand how perceptions are formed by breaking them down into smaller and smaller elements. Then we can analyze how these basic elements are recombined to form a perception. They believed that a perception is simply the sum of its parts.

structured interviews A research technique in which each individual is asked the same set of relatively narrow and focused questions, so that the same information is obtained from everyone.

subgoals In problem solving, a strategy by which the overall problem is broken into separate parts that, when completed in order, will result in a solution.

sublimation A type of displacement in which threatening or forbidden desire, usually sexual, is redirected into socially acceptable forms.

subliminal messages Brief auditory or visual messages that are presented below the absolute threshold, so that their chance of perception is less than 50%.

subliminal stimulus A stimulus whose intensity is such that a person has a less than 50% chance of detecting it.

substance abuse A maladaptive pattern of frequent and continued usage of a substance—a drug or medicine—that results in significant problems, such as failing to meet major obligations and having multiple legal, social, family, health, work, or interpersonal difficulties. These problems must occur repeatedly during a single 12-month period to be classified as substance abuse.

superego Freud's third division of the mind, which develops from the ego during early childhood; its goal is to apply the moral values and standards of one's parents or caregivers and society in satisfying one's wishes.

superstitious behavior In operant conditioning, any behavior that increases in frequency because its occurrence is accidentally paired with the delivery of a reinforcer.

suprachiasmatic nucleus A sophisticated biological clock, located in the hypothalamus, that regulates a number of circadian rhythms, including the sleep-wake cycle. Suprachiasmatic cells are highly responsive to changes in light.

surface structure According to Chomsky, the actual wording of a sentence, as it is spoken.

survey A way to obtain information by asking many individuals—person to person, by telephone, or by mail—to answer a fixed set of questions about particular subjects.

sympathetic division The subdivision of the autonomic nervous system that is triggered by threatening or challenging physical or psychological stimuli, increasing the body's physiological arousal and preparing the body for action.

synapse An infinitely small space (20–30 billionths of a meter) between an end bulb and its adjacent body organ, muscle, or cell body; it is a space over which chemical messages are transmitted.

syntax *See* grammar.

systematic desensitization A technique of behavior therapy, based on classical conditioning, in which a person is gradually and progressively exposed to fearful or anxiety-evoking stimuli while practicing deep relaxation. Systematic desensitization is a form of counterconditioning because it replaces, or counters, fear and anxiety with relaxation.

T

***t* test** An estimate of reliability that takes into account both the size of the mean difference and the variability in distributions.

taijin kyofusho (TKS) A mental disorder found only in Asian cultures, particularly Japan. This social phobia is characterized by a morbid fear of offending others through awkward social or physical behavior, such as making eye-to-eye contact, blushing, giving off an offensive odor, having an unpleasant or tense facial expression, or having trembling hands.

tardive dyskinesia A condition characterized by the appearance of slow, involuntary, and uncontrollable rhythmic movements and rapid twitching of the mouth and lips, as well as unusual movements of the limbs. This condition is a side effect of the continued use of typical neuroleptics.

task-oriented group A group in which members have specific duties to complete.

taste A chemical sense that makes use of various chemicals or stimuli.

taste-aversion learning The association of a particular sensory cue (smell, taste, sound, or sight) with an unpleasant response, such as nausea or vomiting, resulting in future avoidance of that particular sensory cue.

taste buds Onion-shaped structures on the tongue that contain the receptors for taste.

TAT *See* Thematic Apperception Test.

telegraphic speech A distinctive speech pattern observed during language acquisition in which the child omits articles, prepositions, and parts of verbs.

telepathy The ability to transfer thoughts to another person or to read the thoughts of others.

temperament An individual's distinctive pattern of attention, arousal, and reactivity to new or novel situations. This pattern appears early, is relatively stable and long-lasting, and is influenced in large part by genetic factors.

temporal lobe A segment of the brain located directly below the parietal lobe that is involved in hearing, speaking coherently, and understanding verbal and written material.

teratogen Any agent that can harm a developing fetus (causing deformities or brain damage). It might be a disease (such as genital herpes), a drug (such as alcohol), or another environmental agent (such as chemicals).

test anxiety A combination of physiological, emotional, and cognitive components that are caused by the stress of taking exams and that may interfere with a student's ability to think, reason, and plan.

testimonial A statement in support of a particular viewpoint based on personal experience.

testosterone The major male hormone, which stimulates the growth of genital organs and the development of secondary sexual characteristics.

texture gradient In three-dimensional vision, a monocular depth cue: Areas with sharp, detailed texture are interpreted as being closer, and those with less sharpness and detail as more distant.

thalamus A structure of the limbic system that is located in the middle of the forebrain and is involved in receiving sensory information, doing some initial processing, and then relaying the sensory information to appropriate areas of the cortex, including the somatosensory cortex, primary auditory cortex, and primary visual cortex.

Thematic Apperception Test (TAT) A personality test in which subjects are asked to look at pictures of people in ambiguous situations and to make up stories about what the characters are thinking and feeling and what the outcome will be.

theory of evolution Darwin's theory that different species arose from a common ancestor and that those species survived that were best adapted to meet the demands of their environments.

theory of linguistic relativity Whorf's theory that the differences among languages result in differences in the ways people think and perceive the world.

theory of personality An organized attempt to describe and explain how personalities develop and why personalities differ.

thinking Mental processes by which we form concepts, solve problems, and engage in creative activities. Sometimes referred to as reasoning.

threat appraisal Our conclusion that harm or loss has not yet taken place in a particular situation but we anticipate it in the near future.

threat simulation theory of dreams The idea that dreaming serves a biological function by repeatedly simulating events that are threatening in our waking lives so that our brain can practice how it perceives threats and we can rehearse our responses to these events.

threshold A point above which a stimulus is perceived and below which it is not perceived. *See also* absolute threshold.

thyroid A gland located in the neck that regulates metabolism through the secretion of hormones. It forms part of the endocrine system.

time-out In training children, a form of negative punishment in which reinforcing stimuli are removed after an undesirable response. This removal decreases the chances that the response will recur. In time-out, the child is told to sit quietly in the corner of a room or put in some other situation where there is no chance to obtain reinforcers or engage in pleasurable behaviors.

tip-of-the-tongue phenomenon The situation in which, despite making a great effort, we are temporarily unable to recall information that we absolutely know is in our memory.

TKS *See* taijin kyofusho.

TMS *See* transcranial magnetic stimulation.

tolerance The reaction of the body and brain to regular drug use, whereby the person has to take larger doses of the drug to achieve the same behavioral effect.

touch The skin senses, which include temperature, pressure, and pain. Touch sensors change mechanical pressure or changes in temperature into nerve impulses that are sent to the brain for processing.

trait A relatively stable and enduring tendency to behave in a particular way.

trait theory An approach for analyzing the structure of personality by measuring, identifying, and classifying similarities and differences in personality characteristics or traits.

transcendental meditation (TM) A meditation exercise in which individuals assume a comfortable position, close their eyes, and repeat and concentrate on a sound to clear their head of all thoughts (worrisome and otherwise).

transcranial magnetic stimulation (TMS) A noninvasive diagnostic technique that activates neurons by sending pulses of magnetic energy into the brain.

transduction The process by which a sense organ changes, or transforms, physical energy into electrical signals that become neural impulses, which may be sent to the brain for processing.

transference In psychotherapy, the process by which a client expresses strong emotions toward the therapist because the therapist substitutes for someone important in the client's life, such as the client's mother or father. Freud first developed this concept.

transformational rules According to Chomsky, procedures by which we convert our ideas from surface structures into deep structures and from deep structures back into surface structures.

transmitter A chemical messenger that transmits information between nerves and body organs, such as muscles and heart. *See also* neurotransmitters.

transsexualism *See* gender identity disorder.

triangular theory of love *See* Sternberg's triangular theory of love.

triarchic theory *See* Sternberg's triarchic theory.

trichromatic theory The idea that there are three different kinds of cones in the retina, and each cone contains one of three different light-sensitive chemicals, called opsins. Each opsin is most responsive to wavelengths that correspond to each of the three primary colors—blue, green, and red—from which all other colors can be mixed.

two-factor theory A theory of intelligence proposed by Spearman, according to which a general mental ability factor, ***g,*** represents a person's ability to perform complex mental work, such as abstract reasoning and problem solving, while many specific factors, ***s,*** represent a person's specific mental abilities, such as mathematical, mechanical, and verbal skills. Thus, ***g*** is constant across tests, while ***s*** may vary across tests.

two-word combinations The third stage in acquiring language, which begins at about 2 years of age. The infant says strings of two words that express various actions ("Me play," "See boy") or relationships ("Hit ball," "Milk gone").

tympanic membrane The thin, taut membrane, commonly called the eardrum, that is the boundary between the outer ear and middle ear. When struck by sound waves, it vibrates and passes the vibrations to the ossicles.

Type A behavior A combination of personality traits that may be a risk factor for coronary heart disease. According to the original (1970s) definition, these traits included an overly competitive and aggressive drive to achieve, a hostile attitude when frustrated, a habitual sense of time urgency, a rapid and explosive pattern of speaking, and workaholic tendencies; in contrast, type B behavior was easygoing, calm, relaxed, and patient. In the 1980s, the list of traits was reduced to being depressed, aggressively competitive, easily frustrated, anxious, and angry. In the 1990s, the list was reduced again, to frequent feelings of anger and hostility, which may or may not be publicly expressed. Currently, researchers conclude that individuals who either always show their anger and hostility or always suppress it have large increases in physiological arousal, which can have damaging effects on one's heart and health.

Type B behavior Behavior characterized as being easygoing, calm, relaxed, and patient.

Type D behavior Behavior characterized by chronic distress in terms of two emotional states: negative affectivity (worry, irritability, gloom) and social inhibition (shyness, being reserved, lack of self-assurance).

Type I schizophrenia A type of schizophrenia characterized by positive symptoms, such as hallucinations and delusions, which are distortions of normal functions. Individuals diagnosed with Type I schizophrenia have no intellectual impairment, good reaction to medication, and thus a good chance of recovery.

Type II schizophrenia A type of schizophrenia characterized by negative symptoms, such as dulled emotions and little inclination to speak, which are a loss of normal functions. Individuals diagnosed with Type II schizophrenia have intellectual impairment, poor reaction to medication, and thus a poor chance of recovery.

typical neuroleptic drugs Neuroleptics that primarily reduce the levels of the neurotransmitter dopamine. Two of the more common are phenothiazines (for example, Thorazine) and butrophenones (for example, haloperidol). These drugs primarily reduce positive symptoms but have little or no effects on negative symptoms.

U

unconditional positive regard The warmth, acceptance, and love that others show us because we are valued human beings even though we may behave in ways that disappoint them because they differ from their standards and values or the way they think.

unconditioned response (UCR) An unlearned, innate, involuntary physiological reflex that is elicited by the unconditioned stimulus.

unconditioned stimulus (UCS) A stimulus that triggers or elicits some physiological response, such as salivation or eye blink.

unconscious forces Wishes, desires, or thoughts that, because of their disturbing or threatening content, we automatically repress and cannot voluntarily access.

unconscious motivation A Freudian concept that refers to the influence of repressed thoughts, desires, or impulses on our conscious thoughts and behaviors.

unconsciousness Total loss of awareness and responsiveness to the environment. It may be due to disease, trauma, a blow to the head, or general medical anesthesia.

underachievers Individuals who score relatively high on tests of ability or intelligence but perform more poorly than their scores would predict.

universal emotional expressions A number of specific inherited facial patterns or expressions that signal specific feelings or emotional states, such as a smile signaling a happy state.

uplifts Small, pleasurable, happy, and satisfying experiences that we have in our daily lives.

V

validity The extent to which a test measures what it is supposed to measure.

variable-interval schedule A conditioning schedule such that the time between the response and the subsequent reinforcer is variable.

variable-ratio schedule A conditioning schedule in which the subject must make a different number of responses for the delivery of each reinforcer.

variance A measure of the variability within two distributions.

ventrolateral preoptic nucleus (VPN) A group of cells in the hypothalamus that acts like a master switch for sleep. Turned on, the VPN secretes a neurotransmitter (GABA) that turns off areas that keep the brain awake; turned off, the VPN causes certain brain areas to become active and we wake up.

ventromedial hypothalamus A group of brain cells that regulates hunger by creating feelings of satiety, or fullness.

vertigo Feelings of dizziness and nausea resulting from malfunction of the semicircular canals in the vestibular system.

vestibular system Three semicircular canals in the inner ear that sense the position of the head, keep the head upright, and maintain balance. Fluid in the semicircular canals moves in response to movements of the head, and sensors (hair cells) in the canals respond to the movement of the fluid.

virtual reality A perceptual experience—of being inside an object, moving through an environment, or carrying out some action—that is, in fact, entirely simulated by a computer.

visible spectrum The one particular segment of electromagnetic energy that we can see because these waves are the right length to stimulate receptors in the eye.

visual agnosia A condition caused by damage to the visual association area. An individual with visual agnosia is unable to recognize some object, person, or color and yet is able to see and even describe parts of some visual stimulus.

visual association area An area of the brain, located next to the primary visual cortex, that transforms basic sensations, such as lights, lines, colors, and textures, into complete, meaningful visual perceptions, such as persons, objects, or animals.

visual cliff A glass tabletop with a checkerboard pattern over part of its surface; the remaining surface consists of clear glass with a checkerboard pattern several feet below, creating the illusion of a clifflike drop to the floor.

VPN *See* ventrolateral preoptic nucleus.

vulnerability Psychological or environmental difficulties that make children more at risk for developing later personality, behavioral, or social problems.

W

Weber's law A psychophysics law stating that the increase in intensity of a stimulus needed to produce a just noticeable difference grows in proportion to the intensity of the initial stimulus.

Wechsler Adult Intelligence Scale (WAIS) and Wechsler Intelligence Scale for Children (WISC) Intelligence tests that are divided into various subtests. The verbal section contains a subtest of general information, a vocabulary subtest, and so forth. The performance section contains a subtest that involves arranging pictures in a meaningful order, one that requires assembling objects, and one that involves using codes. The verbal and performance scores are combined to give a single IQ score.

weight-regulating genes Genes that play a role in influencing appetite, body metabolism, and secretion of hormones (such as leptin) that regulate fat stores.

Wernicke's aphasia Difficulty in understanding spoken or written words and in putting words into meaningful sentences, as a result of injury to Wernicke's area in the brain.

Wernicke's area An area usually located in the left temporal lobe that plays a role in understanding speech and speaking in coherent sentences. *See* Wernicke's aphasia.

withdrawal symptoms Painful physical and psychological symptoms that occur when a drug-dependent person stops using a drug.

word An arbitrary pairing between a sound or symbol and a meaning.

working memory *See* short-term memory.

Y

Yerkes-Dodson law The principle that performance on a task is an interaction between the level of physiological arousal and the difficulty of the task. For difficult tasks, low arousal results in better performance; for most tasks, moderate arousal helps performance; and for easy tasks, high arousal may facilitate performance.

yoga A meditation exercise that involves a system of breathing techniques, physical exercises, and postures.

Z

zygote The cell that results when an egg is fertilized. It contains 46 chromosomes, arranged in 23 pairs.

Module 1

6: Graph data from "Arithmetic calculation, deep inspiration or handgrip exercise-mediated preoperational active palmar sweating responses in humans," by Masayoshi Kobayashi, Noriko Tomioka, Yoshihisa Ushiyama and Toshio Ohhashi *Autonomic Neuroscience,* Volume 104, Issue 1, pp. 58–65. **17:** Pie chart data from "Psychological Science Around the World," by M. R. Rosenzweig, 1992, *American Psychologist, 47,* 718–22. **21:** Excuses list from "Excuses, Excuses," by D. A. Bernstein, 1993, *APS Observer,* March, 1993, Vol 6, No. 2, p. 4. Copyright © 1993 by the Association for Psychological Sciences. Reprinted by permission of the author.

Module 3

58: Based on an illustration in *Scientific American Mind,* April/May, 2006, p. 18 by Jason Lee. By permission of Jason Lee.

Module 4

68: (right) Chromosome drawing redrawn by permission from an illustration on page 126 by Michael Goodman in "DNA's New Twists," by John Rennie, *Scientific American,* March, 1993. All rights reserved. **79:** (bottom left) From "Language Specificity and Elasticity: Brain and Clinical Syndrome Studies," by M. Maratsos and L. Matheny, 1994, *Annual Review of Psychology, 45,* 487–516. **79:** (bottom right) Adapted from *Left Brain, Right Brain,* by S. P. Springer and G. Deutsch, 4/e, 1989. W. H. Freeman Company. **84:** (houses and letter L) Based on data from *Sex Differences in Cognitive Abilities,* by D. F. Halpern, 2000. Lawrence Erlbuam Associates. **84:** (left) Figures adapted from "Sex Differences in the Brain," by D. Kimura, 1992, *Scientific American, 267,* 119–125.

Module 5

114: (top) Illustration based on K. Daniel Clark from "Newsfronts: Science & Technology," by Dawn Stover, *Popular Science,* August 1997, p. 29. Reprinted by permission.

Module 8

188: Adapted from "How AA Works and Why It's Important for Clinicians to Understand," by E. J. Khantzian and J. E. Mack, 1994, *Journal of Substance Abuse Treatment, 11,* 77–92.

Module 9

196: Graph data from "Pitch Discrimination in the Dog," by H. M. Anrep, 1920, *Journal of Physiology, 53,* 367–385. **206:** Graph adapted from "Emotional Fainting and the Psychophysiologic Response to Blood and Injury: Autonomic Mechanisms and Coping Strategies," by A. Steptoe and J. Wardle, 1988, *Psychosomatic Medicine, 50,* 402–417.

Module 10

214: Graph on right based on data from *Behavior of Organisms,* by B. F. Skinner, 1938. Appleton-Century-Crofts. **215:** Skinner box illustration from *Introduction to Psychology,* by E. Bruce Goldstein, 1995. Brooks/Cole. **216:** Adapted from "Treating Chronic Food Refusal in Young Children: Home-Based Parent Training," by M. A. Werle, T. B. Murphy & K. S. Budd, 1993, *Journal of Applied Behavior Analysis, 26,* 421–433. **220:** Reinforcement diagram from *Psychology: Themes and Variations,* by Wayne Weiten, 2nd ed., figure 6.13. Copyright © 1992 by Wadsworth, Inc. Reproduced by permission. **221:** Based on data from the U.S. Department of the Navy and an illustration by Suzy Parker, *USA TODAY,* March 27, 2003, p. 8D. **223:** (left) Skinner box illustration from *Introduction to Psychology,* by E. Bruce Goldstein, 1995. Brooks/Cole. **225:** Bar graph data from "Relative Efficacy of Densensitization and Modeling Approaches for Inducing Behavior, Affective and Attitudinal Changes," by A. Bandura, E. B. Blanchard & B. Ritter, 1969, *Journal of Personality and Social Psychology, 13,* 173–179. **227:** (top, #1) Skinner box illustration from *Introduction to Psychology,* by E. Bruce Goldstein, 1995. Brooks/Cole. **234:** (#1 graph) Adapted from "Treating Chronic Food Refusal in Young Children: Home-Based Parent Training," by M. A. Werle, T. B. Murphy & K. S. Budd, 1993, *Journal of Applied Behavior Analysis, 26,* 421–433.

Module 11

253: Bar graph data from "Repeated Memory of Oral Prose in Ghana and New York," by B. M. Ross and C. Millson, 1970, *International Journal of Psychology, 5,* 173–181. **253:** Excerpt from *Remembering: A Study in Experimental and Social Psychology,* by F. C. Bartlett, p. 65, 1932. Cambridge University Press. Copyright © 1932. Reprinted with the permission of Cambridge University Press. **255:** Adapted from "Vivid Memories," by D. C. Rubin and M. Kozin, 1984, *Cognition, 16,* 81–95. Copyright © 1984 by Elsevier Science Publishers BV. Adapted by permission from Elsevier Science.

Module 12

261: Adapted from "Nearly 2,000 Witnesses Can Be Wrong," by R. Buckout, 1980, *Bulletin of the Psychonomic Society, 16,* 307–310. **262:** Memory figure based on *Learning and Memory,* by D. A. Norman, 1982. W. H. Freeman & Company. **263:** Network hierarchy based on "Retrieval time from semantic memory," by A. M. Colins and M. R. Quillian, 1969, *Verbal Learning and Verbal Behavior, 8,* 240–247. **270:** (#4) Graph data from "Fifty Years of Memory for Names and Faces," by H. P. Bahrick, P. O. Bahrick & R. P. Wittlinger, 1975, *Journal of Experimental Psychology: General, 104,* 54–75. **276:** (#5) Graph data from "Fifty Years of Memory for Names and Faces," by H. P. Bahrick, P. O. Bahrick & R. P. Wittlinger, 1975, *Journal of Experimental Psychology: General, 104,* 54–75.

Module 13

287: (center) Graphs adapted from "Age and WAIS-R A Cross-Sectional Analysis with Educational Level Controlled," by A. S. Kaufman, C. R. Reynolds & J. E. McLean, 1989, *Intelligence, 13,* pp. 246, 247. Copyright © 1989 by Ablex Publishing Company. Adapted by permission. **294:** Source: Hernstein and Murray, 1994. **295:** (right, #7) Graph adapted from "Age and WAIS-R A Cross-Sectional Analysis with Educational Level Controlled," by A. S. Kaufman, C. R. Reynolds & J. E. McLean, 1989, *Intelligence, 13,* pp. 246, 247. Copyright © 1989 by Ablex Publishing Company. Adapted by permission.

Van Heck, L. Van Langenhove & K. S. Yang, 1990, *Journal of Cross-Cultural Personality, 21,* 5–47, and additional data from "Mate Preferences in 37 Cultures," by D. M. Buss. In W. J. Lonner & R. Malpass (Eds.), *Psychology and Culture.* Allyn & Bacon.

Module 19

450: (right) From *Abnormal Psychology,* by Barlow/Durand, 2/E, p. 79. Copyright © 1997. Brooks/Cole Publishing.

Module 20

467: Bar graph data from "Genes, Environment, and Personality," by T. J. Bouchard, 1994, *Science, 264,* 1700–1701. American Association for the Advancement of Science. Additional data from Bouchard & Loehlin, 2001. **468:** Bar graph data from "Genes, Environment, and Personality," by T. J. Bouchard, 1994, *Science, 264,* 1700–1701. American Association for the Advancement of Science. Additional data from Bouchard & Loehlin, 2001, Plomin & Crabbe, 2000.

Module 21

483: Situation list data from *USA Today,* August 19, 1987, p. 4D. **486:** List adapted from "The Factor Structure of Self-Reported Physical Stress Reactions," by J. C. Smith and J. M. Seidel, 1982, *Biofeedback and Self-Regulation, 7,* 35–47. Springer Netherlands. **490:** Scale: Reprinted from "Life changes scaling for the 1990s," by M. A. Miller and R. H. Rahe, *Journal of Psychosomatic Research, 43,* 279–292, Copyright © 1997, with permission from Elsevier Science. **501:** Graph data from "Body Temperature Changes During the Practice of g Tum-mo-Yoga," by H. Benson, J. W. Lehmann, M. S. Malhotra, R. F. Goldman, P. J. Hopkins & M. D. Epstein, 1982, *Nature, 295,* 234–235. **505:** (#19) Graph data from "Body Temperature Changes During the Practice of g Tum-mo-Yoga," by H. Benson, J. W. Lehmann, M. S. Malhotra, R. F. Goldman, P. J. Hopkins & M. D. Epstein, 1982, *Nature, 295,* 234–235.

Module 22

514–515: Syndrome titles from *Diagnostic and Statistical Manual of Mental Disorders,* Fourth Edition. Copyright © 1994 American Psychiatric Association. **518:** (bottom) Bar graphs data on phobias from "Panic and Phobia" by W. W. Eaton, A. Dryman & M. M. Weissman, 1991. In L. N. Robins & D. A. Regier (Eds.), *Psychiatric Disorders in America: The Epidemiological Catchment Area Study.* Free Press.

Module 23

531: (Chuck Elliot) Adapted from "Breakdown into the Shadows of Mental Illness," by C. Brooks, *San Diego Union-Tribune,* February 27, 1994, p. 4. **531:** (Michael McCabe) Adapted from "Shadowland: Three Profiled in Mental Illness Series Are Striving to Improve Their Condition" by C. Brooks, *San Diego Union-Tribune,* February 27, 1995. **535:** Excerpt from "Electroboy," by Andy Behrman. Copyright © 1999. Reprinted by permission of the author. **539:** Bar graph data from *Schizophrenia Genesis: The Origins of Madness,* by I. I. Gottesmann, 1991. W. H. Freeman & Company; with additional data from "The Epidemiology of Schizophrenia in a Finnish Twin Cohort," by T. D. Cannon, J. Kaprio, J. Lonnqvist, M. Huttunen & M. Koskenvuo, 1998, *Archives of General Psychiatry, 55,* 67–74. **543:** (#5) Bar graph data from "Current Perspectives on the Genetics of Unipolar Depression," by S. O. Moldin, T. Reich & J. P. Rice, 1991, *Behavior Genetics, 21,* 211–242. **543:** (#7) ECT treatment graph adapted from "Use of ECT with Treatment-Resistant Depressed Patients at the National Institute of Mental Health," by S. M. Paul, I. Extein, H. M. Calil, W. Z. Potter, P. Chodiff & F. K. Goodwin, 1981, *American Journal of Psychiatry, 138,* 486–489. **547:** Bar graph data from "Exercise treatment for major depression: Maintenance of therapeutic benefits at 10 months," by M. Babyak, et al., 2000, *Psychosomatic Medicine, 62,* 633–638.

Module 24

560: Therapy session adapted from "A Critique of So-Called Standard Psychoanalytic Technique," by S. D. Lipton, 1983, *Contemporary Psychoanalysis, 19,* 35–52. **564:** Therapy session adapted from "Person-Centered Therapy," by N. J. Raskin and C. R. Rogers, 1989. In R. J. Corsini and D. Wedding (Eds.), *Current Psychotherapies,* 4th ed. F. E. Peacock. **565:** Therapy session adapted from *Cognitive Therapy of Depression,* by A. T. Beck, A. J. Rush, B. F. Shaw & G. Emery, 1979, pp. 145–146. Guilford Press. **566:** Therapy session adapted from *Clinical Behavior Therapy,* by M. R. Goldfried and G. C. Davison, 1976. Holt, Rinehart & Winston.

Module 25

592: Asch study based on "Effects of Group Pressure Upon Modification and Distortion of Judgements," by Solomon Asch, 1958. In E. Maccoby, T. M. Newcomb & E. L. Hartley (Eds.), *Readings in Social Psychology* (3rd Ed.). Holt, Rinehart & Winston. **606:** (#8) Bar graph data from "Improving the Academic Performance of College Freshman," by T. D. Wilson and P. W. Linville, 1982, *Journal of Personality and Social Psychology, 42,* 367–376, American Psychological Association.
